[Cingulum bundle](#)

Definition

The cingulum, also known as the cingulum bundle, is a fiber tract in the brain that connects the cingulate gyrus, found in the midline of the brain above the corpus callosum, to the entorhinal cortex, found in the base of the anterior temporal lobe. The tract lies between the cingulate gyrus and the corpus callosum, curving around the back of the callosum and extending into the anterior temporal lobe. The brain structures that the cingulum connects both belong to the limbic system, which is involved in the experience and regulation of emotional states as well as memory. The cingulate gyrus has many functions including helping to selectively attend to relevant stimuli in the environment. Thus, the cingulum may send attended signals from the cingulate gyrus into a pathway that allows salient information to become encoded into long-term memories. Imaging

research using diffusion tensor imaging consistently finds reduced fractional anisotropy, a measure of white matter integrity, in the cingulum bundle among individuals with autism, and in many studies, this abnormality correlated with the degree of social impairment. In individuals without autism but with brain lesions affecting the cingulum, the degree of disruption of this pathway related to mentalizing impairment. This suggests that the cingulum bundle plays an important role in aspects of social cognition that are impaired in autism, and that differences in the development of this pathway may underlie some features of ASD.

Circle of Friends

Howard Goldstein

Human Development and Family Science, The Ohio State University, Columbus, OH, USA

Definition

Circle of friends is a conceptual framework that has been used to develop interventions to promote inclusion of individuals with disabilities in mainstream settings through relationship development with peers, especially individuals at particular risk of rejection or social isolation. A more specific definition refers to “circle of friends” as a group of people who gather around a person who has become excluded or isolated (Falvey et al. 1997).

Historical Background

The circle of friends intervention was initially developed in Canada to facilitate the deinstitutionalization of people with disabilities transitioning to their local communities. Circle of friends was subsequently applied to supporting the inclusion of pupils with special needs in their local mainstream schools (Forest and Lusthaus 1989). Circle of friends also was adapted to support children experiencing emotional, behavioral, and social difficulties in schools (Newton et al. 1996; Pearpoint et al. 1996). The basic implementation of circle of friends involved enlisting the help of classmates through conducting a whole-class meeting and then setting up a voluntary, special group or a “circle of friends.” This circle of friends group helps to set, monitor, and review weekly targets in a meeting facilitated by an adult. Parents also have been encouraged to establish circle of friends (Turnbull et al. 1999). Other social skills interventions that have involved peer-mediated interventions, such as peer buddies (e.g., English et al. 1997) or peer support networks (e.g., Haring and Breen 1992), have sometimes been referred to as consistent with the circle of friends approach.

Rationale or Underlying Theory

The original conceptualization of circle of friends was graphically represented by a set of concentric circles. The center of the circle represents the individual with a disability who is the focus of intervention. The second circle is called the circle of intimacy and includes people who are called “anchors.” This circle represents the close relationships that one cannot live without. The third circle is called the circle of friendship and includes people who are called “allies.” The circle represents friends and close relatives. They are people one can count on in difficult times and who one can confide in. If friendship relationships are sparse, one is prone to isolation, and this may result in anger and depression. The fourth circle is the circle of participation and includes people who are called “associates.” Associates are people with whom one may interact in the community, in

school, in houses of worship, etc. The fifth circle is the circle of exchange and includes people who are “paid.” This would encompass interactions with teachers, aides, medical providers, therapists, hairdressers, etc. People with disabilities may interact with more than the usual number of paid members. These individuals appear to set the agenda for the person with disabilities through scheduled appointments, policy requirements, and their limited availability.

These concentric circles are sometimes referred to as circles of support. They can change over time, especially at life transitions that may change the cast of people in one’s life. This model recognizes the stability of the inner circle of intimacy, but points out that other relationships are important to develop human potential and experience. In particular, the circle of friends intervention emphasizes the need to grow the circle of friendship to maximize inclusion of the person with disabilities in mainstream society and to minimize the likelihood of isolation from or within natural community settings. Building the circle of friendship changes the people who may be moving from other circles, e.g., “associates,” as well as the person with the disability who is at the center of the circle.

As described below, the people in the circle of friendship are provided information to deepen their appreciation of the person at the center of the circle, the characteristics of their disorder, as well as their individual strengths, interests, and desires. They are called upon to identify targets that will enhance the social inclusion of the person, to assist with the learning process, and to track progress. Ultimately, the persons in the peer group are expected to develop authentic friendships characterized by supportive, reciprocal relationships that will expand social inclusion as the person with disabilities learns to adapt successfully to a growing set of social circumstances.

Goals and Objectives

The goal of circle of friends programs is to promote social inclusion of individuals at risk of

rejection or isolation from the community. Circle of friends programs could promote increased support within the different circles or levels, such as extended family, friends, neighbors, and faith communities, but the main objective is to increase the circle of friendship.

Treatment Participants

Circle of friends has been applied to a variety of populations of individuals of all ages with disabilities. Applicability to individuals with autism is readily apparent, as social and communication skills tend to be an area of weakness that typically must be addressed to promote social inclusion of individuals with autism. Peer approaches to promoting social inclusion are prevalent in preschool settings, but have been applied to school age and older individuals as well. Transitions to different school, vocational, and residential settings are each likely to require a reevaluation of one's circle of friends and the need for additional efforts to provide supportive social partners at various levels.

Treatment Procedures

Interventions deemed most consistent with the circle of friends framework are likely to begin with filling in names in the concentric circles of anchors, allies, associates, and paid members. The interventionist uses this information to illustrate the importance of peer friendships, rather than relationships with mainly paid adults. The intervention program usually provides new and accurate information about the nature of the disability, such as the characteristics of autism, and the nature of increased support among allies and associates in particular. Peers are called upon to identify positive features or assets of the individual who is the focus of intervention. As peers discuss strengths, interests, preferences, and desires of their peer with autism, they are guided to recognize that everybody has their own special abilities and areas of needs. The overlap between features of autism and the areas that they may find difficult

when interacting with their peer with autism are highlighted. The peers are encouraged to discuss their own strengths and weaknesses as well. This process is meant to increase social acceptance as well as identifying unique needs or skills that the peers might help the individual with disabilities master to increase acceptance. Weaknesses are discussed as "things one is still learning to do." Thus, the peers are given primary responsibility for helping identify social targets and identifying ways to encourage learning on the part of the person with a disability. They also may be asked to track progress and to be sensitive to new skills that might be needed to adapt to a growing array of social situations. An adult facilitator typically meets with a group of peers and the person with the disability on a regular basis to help sustain the effort and ensure that interactions are supportive, encouraging, and acceptable to all involved.

A number of peer buddy and peer network interventions have been considered exemplars of circle of friends programs, although they have not been developed from the circle of friends conceptual framework.

Efficacy Information

Few evaluations of circle of friends programs have been conducted. Many of those evaluations have reported encouraging results using qualitative case study methodologies or have been largely descriptive in nature (Barrett and Randall 2004; Calabrese et al. 2008; Gus 2000; Newton et al. 1996; Whitaker et al. 1998). A lack of a standard treatment protocol hinders replication and makes evaluations of circle of friends difficult.

Small-scale group design studies have shown improvements in social skills compared to comparison groups (Kalyva and Avramidis 2005). On the other hand, Frederickson and colleagues (Frederickson et al. 2005) found that improved social acceptance on the part of classmates tended to diminish over time and there were no discernable long-term effects seen in the social skills of primary grade children with autism. Owen-DeSchryver et al. (2008) employed peer training

based at least in part on circle of friends and showed, in a multiple baseline design across peer groups, that peers' initiations increased after training and a corresponding increase in initiations and responses was seen in children with ASD. An examination of the single-subject graphs reveals a strong correspondence between peer behavior and the corresponding social behavior of the children with autism. Long-term maintenance and generalization of effects were not evaluated, however. Miller et al. (2003) also used a multiple baseline design across peers and found improved social skills during lunchtime following friendship circle training. They also found impressive maintenance and generalization to recess and other activities for two of the three participants.

Peer-mediated interventions have repeatedly been shown to have robust effects on improving the social behavior of young children with autism (McConnell 2002; Rogers 2000). However, there are few studies that evaluate maintenance of effects and the extent to which peer relationship development results. Perhaps more consistent with the circle of friends framework is the promising research on peer support networks that have been shown to be efficacious in promoting pro-social behavior in youth with ASD (e.g., Haring and Breen 1992; Harrell et al. 1997; Hughes et al. 1999).

Outcome Measurement

One measure of the effects of circle of friends programs is an assessment of the number of people who are identified and who identify themselves within the circles of friendship. In addition, sociometric ratings can be used to determine whether the individual has an elevated social status within a classroom or another social network. Social network analyses also could be used to determine whether individuals with disabilities move from the periphery to more central roles with more reciprocal friendship nominations.

Observational data collection systems typically monitor the rate of social initiations and responses. Alternatively, they could monitor

more specific, targeted behaviors. For example, subsequent to circle of friends training, annoying or disruptive behaviors might be expected to occur less often and appropriate topic shifts, sharing, complimenting, or other positive social behaviors being learned might be expected to occur more frequently.

Social skills rating scales also are available that can be administered to teachers, parents, or peer groups.

Qualifications of Treatment Providers

Circle of friends programs have been implemented by a variety of professionals, including teachers, special educators, counselors, speech-language pathologists, as well as parents.

Circumstantial Thinking

► Circumstantiality

Circumstantiality

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Circumstantial thinking](#)

Definition

A pattern of speech characterized by provision of a mix of relevant and irrelevant information seen in some psychiatric disorders. Typically, although some aspects of narrative are present, the inclusion of extraneous detail and only minimally relevant (or irrelevant) information makes it difficult to follow the speaker's thought. Often individuals need to be reminded of the topic or question because they lose track of the topic. Typically the patient has difficulty in separating relevant from irrelevant information while describing an event. The patient often includes all details and presents them in a sequential order, with the result that the main thread of thought becomes lost as one association leads to another. Frequently the person may need to have questions repeated because the main point of answers has become lost in the confusion of unnecessary detail. Circumstantial thinking/speech is most commonly seen in schizophrenia and obsessive compulsive disorder. It can also be observed in some neurological syndromes (including epilepsy syndromes) at the interface of neurology and psychiatry. Individuals with Asperger's disorder may have difficulties with monitoring conversational cues and often provide tremendous detail

about topics of special interest but usually remain highly focused on their topic.

Citalopram

Lawrence David Scahill
Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA
Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA
Department of Pediatrics, Emory University, Atlanta, GA, USA

Synonyms

[Escitalopram](#)

Definition

Citalopram is a selective serotonin reuptake inhibitor (SSRI) used to treat depression and anxiety disorders. A large-scale, multisite trial of citalopram in 149 children with autism spectrum disorders showed that it was no better than placebo for reducing repetitive behavior. Citalopram is chemically related to the newer SSRI, escitalopram, which is a single chemical isomer of the molecule. By contrast, citalopram is a so-called racemic mixture, which means that there are two isomers in citalopram.

Citrate and Autism

Jonathan Kopel
Texas Tech University Health Sciences Center (TTUHSC), Lubbock, TX, USA

Synonyms

[Citric acid](#)

Definition

Cytoplasmic citrate is an important metabolite at the junction of many important metabolic

pathways, including the tricarboxylic acid (TCA) cycle and the generation of NADH and FADH₂ (Bhutia et al. 2017). The TCA cycle generates citrate within the mitochondrial matrix via citrate synthase (Bhutia et al. 2017). In a well-fed state, citrate is transferred either across the inner mitochondrial membrane through SLC25A1 or from the plasma to the cytoplasm via SLC13A5 (Bhutia et al. 2017). In the cytoplasm, citrate has multiple biological functions related to metabolic regulation and fatty acid and cholesterol synthesis (Bhutia et al. 2017). Increased cytoplasmic citrate inhibits glycolysis by inhibiting the rate-limiting enzyme phosphofructokinase-1 and stimulates gluconeogenesis by activating fructose-1,6-bisphosphatase. Known as SLC13A5 deficiency, patients present with early-onset epilepsy within the first few weeks after birth and persist during childhood. In addition, these patients exhibit developmental delay, slow progression of motor function, and significant impairment in language and speech development, which does not respond to ketogenic diet (Bhutia et al. 2017). Interestingly, these patients also present with defects in teeth development, identified as microdontia (Bhutia et al. 2017). The early onset and severity of epilepsy in SLC13A5-deficiency suggest citrate might serve as an important energy source for neurons. A loss of function of SLC13A5 may increase seizure susceptibility and delay brain development in SLC13A5 patients through an increased energy deficit.

Similar to SLC13A5 deficiency, it is possible that part of the neurological and social deficits observed in autism spectrum disorder (ASD) patients may result from energy deficits within the brain. A recent study examining the bioenergetics of ASD patients found a correlation with poor social function and behavior with increased citrate synthase activity (Delhey et al. 2017). It is believed that dysregulation of mitochondrial metabolism leads to neurodegeneration, oxidative stress, and neuroinflammation, which can drive microglial function and cell loss (Delhey et al. 2017). However, a randomized case-control study of ASD patients from rectal and cecum

biopsies showed ASD patients had a higher complex I activity, while no change was detected in the complex IV or citrate synthase activity (Rose et al. 2017). The results suggest multiple ETC complexes are upregulated in ASD patients (Rose et al. 2017). However, a preliminary communication showed that ASD children had a lower complex I activity although the sample size for the study was small (Giulivi et al. 2010). Overall, the symptomology of ASD seems to be directly affected by the bioenergetics of the brain and activity of mitochondria.

Civil Rights Act of 1964

Annemarie M. Kelly and Christina N. Marsack-Topolewski

College of Health and Human Services, Eastern Michigan University, Ypsilanti, MI, USA

Definition

The Civil Rights Act of 1964 (the “Act”) is a landmark United States federal law that established several new categories of legal protections for individual civil rights (Pub. L. No 88-352). The Act confirms that it is illegal under the US Constitution for private individuals, businesses, and government agencies to discriminate against people on the basis of their race, skin color, religion, sex, or national origin.

The Act requires fair and equitable treatment in employment, voting, and the distribution of government benefits. Additionally, the Act mandates that all people on the US land have equal access to public facilities and places of public accommodation, including hospitals, clinics, schools, and courthouses, among others. Since 1964, this pivotal Act has served as the legal basis for several other equal opportunity and employment discrimination laws (Sandoval-Strausz 2005). Lawmakers have used the Act’s provisions to create protections for the equitable provision of healthcare services as well as protections for workers with disabilities.

Principles of the Civil Rights Act of 1964

The Civil Rights Act of 1964 strengthened the enforcement of anti-segregation laws. It protects against discriminatory acts that fall within one of five protected categories: race, skin color, religion, sex, and national origin. The Act contains 11 segments called Titles. Certain titles have generated a number of important cases in US federal and state courts. These landmark provisions

prohibit discrimination in voting (Title I), public accommodations (Title II), federal funding and benefits (Title VI), and employment (Title VII). Though these key titles are usually referred to with Roman numerals, they are also sometimes written as Sections One, Two, Six, and Seven, respectively.

Title I bars unequal state voter registration requirements for federal elections. Title II bans racial segregation and other discriminatory acts in public places, including courthouses, parks, restaurants, theaters, sports arenas, hotels, and hospitals (U.S. Department of the Interior 2016). The Act’s Title VI prohibits the federal and state governments from discrimination in providing benefits and services. Title VI impacts any program or activity that uses federal funding (U.S. Department of Health and Human Services 2014).

Today, Title VII of the Act is commonly cited in employee-employer human relations lawsuits and administrative court filings across the country. Title VII prohibits harassment and unequal treatment on the basis of race, color, religion, sex, or national origin in all areas of employment. This covers hiring advertisements, on-the-job tasks, terminations, and retirement matters. The Act prohibits retaliation whenever an individual communicates a discrimination concern, files a discrimination charge, or participates in an employment discrimination investigation or lawsuit against an employer (U.S. Department of Labor 2020). Under Title VII, employers must reasonably accommodate the sincerely held religious practices of all job applicants and employees. An employer’s accommodation is deemed as unreasonable – and, therefore, not legally required – if the accommodation would impose an undue hardship on the operation of the employer’s business. US judicial opinions and administrative laws contain examples of situations with “undue hardships” and types “reasonable accommodations” that are recognized under the Civil Rights Act of 1964.

Over the years, judicial court opinions from the US Supreme Court and case decisions from other lower courts have established guidance

for interpreting the Act's various provisions (often called "legal precedent"). Federal and state administrative rules also provide legal insight about the Act's requirements in specific circumstances. This information is available online in the form of agency regulations, registers, manuals, and memoranda (e.g., U.S. Department of Justice Civil Rights Division Federal Coordination and Compliance Section 2016; U.S. Department of Justice Civil Rights Division 2019).

The Civil Rights Act of 1964 is one of several other civil rights statutes within the U.S. Code. Before 1964, the U.S. Congress passed six other laws that used the title "Civil Rights Act." These laws are the Civil Rights Act of 1866, Civil Rights Act of 1870, Civil Rights Act of 1871, Civil Rights Act of 1875, Civil Rights Act of 1957, and Civil Rights Act of 1960 (U.S. Library of Congress 2020). The earliest statutes contained anti-discrimination requirements; however, several protections were ultimately erased by unsound Supreme Court decisions in the late nineteenth century. In a collection of five cases in 1883, the Supreme Court claimed that Congress did not have the Constitutional power to create legislation that prevented racial discrimination by private individuals (*Civil Rights Cases*, 109 U.S. 3 (1883)). Modern courts have since invalidated these rulings and confirmed that the Supreme Court's interpretations of the Constitution in 1883 were legally incorrect. The Civil Rights Act of 1964 both reinserted and strengthened discrimination protections within the US Code.

After 1964, many pivotal laws were modeled after the Civil Rights Act of 1964, including the Americans with Disabilities Act (ADA) (American Bar Association 2004). As a general rule, all civil rights statutes seek to confirm that all people on US land – citizens, residents, and visitors – have fundamental protections against discrimination that are derived from the U.S. Constitution (U.S. Department of Health and Human Services Office for Civil Rights 2020).

Healthcare Discrimination and the Civil Rights Act of 1964

This ground-breaking Act was instrumental in increasing racial equality and fair government funding in health care services settings. As Longest (2016) explains, the Civil Rights Act of 1964 overturned the discriminatory provisions of the Hill-Burton Act of 1946 (more formally known as the Hospital Survey and Construction Act, Pub. L. No. 725). The Hill-Burton Act allocates government funds for the construction and improvement of hospitals across the United States. Before the Civil Rights Act of 1964, the Hill-Burton Act embraced discriminatory "Separate but Equal" Doctrine, which made it legal for patients to be treated in segregated facilities. The Hill-Burton Act incorrectly assumed that patients could receive equal treatment in divided locations. The Civil Rights Act of 1964 removed the "Separate but Equal" provisions in the Hill-Burton Act (U.S. Commission on Civil Rights 1965).

In passing the Civil Rights Act of 1964, the US Congress confirmed that quality of healthcare, available goods, and government funds distributions can never be truly equitable across segregated locations (Hahn et al. 2018). The Civil Rights Act of 1964, in conjunction with seminal Supreme Court rulings like *Brown v. Board of Education*, confirmed that "Separate but Equal" Doctrine violates the law of the US Constitution (347 U.S. 483 (1954)).

Increased Recognition of Discrimination Issues as Social Determinants of Health

Individuals with autism spectrum disorder (ASD) and their caregivers should be knowledgeable about the anti-discrimination protections that are afforded by the Civil Rights Act of 1964 and its legal precedent. It is well-documented that individuals with ASD and

other disabilities are especially vulnerable to experiences of discrimination (e.g., Trump and Ayres 2020; U.S. Department of Health and Human Services Office of Disease Prevention and Health Promotion 2020a). To be actionable under the Civil Rights Act of 1964, a discriminatory action must relate to at least one of the Act's five protected categories.

The US government agencies and the scientific community have increasingly recognized a correlation between discrimination and negative health outcomes (Rosenbaum et al. 2000). At a high level, discrimination is understood as a social stressor that has a physiological effect on individuals (e.g., irregular heartbeat, anxiety, heartburn). Compounded over time, instances of discrimination can lead to long-term negative health outcomes (Pascoe and Richman 2009). The U.S. Department of Health & Human Services (DHHS) classifies discrimination as one of the "Social Determinants" of people's health (U.S. DHHS Centers for Disease Control and Prevention 2019). Social Determinants of Health (sometimes abbreviated as "SDOH") are "conditions in the environments in which people are born, live, learn, work, play, worship, and age that affect a wide range of health, functioning, and quality-of-life outcomes and risks" (U.S. DHHS Office of Disease Prevention and Health Promotion 2020b). SDOH conditions can forecast increased risks of health challenges. Guidance from the DHHS states,

Discrimination can be attributed to social interactions that occur to protect more powerful and privileged groups at the detriment of other groups. While not all stressful experiences negatively affect health, or occur because of discrimination, many do impact health and can be related to discrimination. (U.S. DHHS Office of Disease Prevention and Health Promotion 2020a)

A growing body of scholarly literature emphasizes that individual and structural discrimination can cause intentional or unintentional harm and negative health consequences, regardless of whether it is perceived by an individual or group (e.g., Krahn et al. 2015; Kirschner et al. 2007; Lewis et al. 2009; Major et al. 2018).

History

The Act's provisions were heavily debated in the 88th US Congress (U.S. Government Publishing Office 2020). The House of Representatives approved the Act on February 10, 1964. On June 19, 1964, it was approved in the Senate. President Lyndon B. Johnson signed the Act into law on July 2, 1964.

CABS; Clancy autism behavior scale

Description

The Clancy Behavior Scale is an early autism descriptive and classification tool first published in 1969 by Clancy, Dugdale, and Rendle-Short in order to better describe and classify autism in young children. Mothers provided reports of child difficulty across 14 major domains, and the instrument was suggestive of “infantile autism” if seven or more of these domains were endorsed as areas of concern.

Historical Background

In the mid-to-late 1960s, the clinical researchers Helen Clancy, Alan Dugdale, and John Rendle-Short in the Department of Child Health from the University of Queensland, Brisbane, Australia, attempted to develop a tool for more reliably describing and accurately identifying young children with autism. They suggested that accurate

classification could be enhanced by identifying significant vulnerabilities across a 14-point major manifestation scale including great difficulty in mixing and playing with other children, acts as deaf, strong resistance to any learning, lack of fear about realistic dangers, resists change in routine, prefers to indicate needs by gestures, laughing and giggling for no apparent reason, not cuddly as a baby, marked physical overactivity, no eye contact, unusual attachment to a particular object or objects, spins objects especially round ones, repetitive and sustained odd play, and standoffish manner. While the scale promoted the use of specific tools and rating systems for improved descriptive and classification purposes, it was not extensively studied or utilized across clinical populations over time.

Psychometric Data

Fairly limited data regarding the scale’s psychometric properties is available. Capute et al. (1975) conducted a prospective study of 200 children to evaluate the reliability and validity of the Clancy Behavioral Scale. Using only the scale, 48 of 200 children met cutoffs for autism risk; however, only one of these children actually fulfilled Kanner’s (1943) criteria for infantile autism. These false positives were suggested to correlate with increasing severity of cognitive deficits, learning disorders, and hearing loss.

Clinical Uses

This scale utilizes parent report of behavior to indicate symptoms across 14 symptoms of infantile autism. The scale has not been extensively studied, nor is it commonly utilized across clinical populations at present. However, it has seen increasing use by research teams in China (Wu et al. 2017; Sun et al. 2013, 2014; Chen et al. 2007; Ke et al. 2002) in screening for autism, investigating prevalence, validating Mandarin-language screening tools, and differentiating

between other language, cognitive, and behavioral disorders.

Classical Conditioning

Jennifer Wick

Community Consultation Program, Division of Neurodevelopmental and Behavioral Pediatrics, University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

Synonyms

[Associative learning](#); [Pavlovian conditioning](#)

Definition

The learning phenomena behind Pavlov's oft-cited salivating dogs (Pavlov 1927) or Little Albert's terror and crying in response to a white rat (Watson and Rayner 1920) are perhaps more scientifically extraordinary than are common sense. It is a unique phenomenon that demonstrates the intricacies of how the brain forms memories and makes meaning. Classical conditioning, or "Pavlovian conditioning," is a type of associative learning. The association between stimuli, or events that are linked in close timing, may be solidified after one or two pairings of the events in close succession. For example, most of us know that a flash of lightning (visual stimuli) will likely result in a thunderous boom (auditory stimuli), which can be loud and frightening. When an individual cringes/winces at the lightning, instead of and before the thunder is emitted, classical conditioning has occurred – that is, the lightning became a "conditioned" trigger for fear. In anticipation of the thunder, the individual reacts to the lightning and not the thunder itself.

Classical conditioning explains a broad number of phenomena in our everyday learning. Not to be confused with operant conditioning, which is a closely related form of associative learning (and the learning phenomenon upon which applied behavioral analysis is based; see Skinner 1953, 1957), classical conditioning is the learning that results from associating two closely timed events: the salivating that takes place upon a dinner bell, instead of for the actual food itself; the sexual

Class Versus Variable

► [Dimensional Versus Categorical Classification](#)

response evoked by a familiar scent or perfume, without the presence of the actual person associated with the memory. Classical conditioning can result in fear, hunger, and sexual and sleep responses, conditioned to a once-neutral event or stimulus. Thus, it is a human ability to predict or anticipate an upcoming pleasurable or aversive event (Rescorla and Wagner 1972). The prediction and anticipation may generalize to other similar stimuli.

Though mathematical models and contemporary descriptions of “configural encoding” have been developed to account for and/or predict the complexities of classical conditioning (Rescorla and Wagner 1972; Rescorla 2003), the occurrence is visible in everyday events. Any environmental event that pairs the human senses (i.e., stimuli) and human need or emotion is a prime opportunity for classical conditioning to take place.

In the applied field of autism intervention and treatment research, classical conditioning approaches take a backseat to operant conditioning approaches. However, a classical conditioning procedure, systematic desensitization, has been used to reduce unwanted fear in children with autism (Love et al. 1990); this procedure involves gradually increasing the intensity of a fear-evoking stimulus. Classical conditioning has also been used in laboratory studies of characteristics associated with autism. For example, Stanton, Peloso, Brown, and Rodier (2007) found that classical conditioning of an eyeblink response occurred more rapidly in a rodent model of autism than in other rodents. Similarly, Sear, Finn, and Steinmetz (1994) found more rapid eyeblink conditioning in children with autism than in typically developing children.

Classroom Management

Susan A. Mason

Services for Students with Autism Spectrum Disorders, Montgomery County Public Schools, Silver Spring, MD, USA

Definition

Classroom management refers to ways of organizing resources, students, procedures, and routines of a classroom so that teaching and learning can proceed in a safe and effective manner.

Historical Background

Historically, specialists in the field of education state that classroom management encourages the establishment of student self-control through positive achievement and behavior. Classroom management is closely linked to issues of motivation, establishing a climate of respect between classroom staff and students and also consistent discipline. The teacher is at a huge advantage when she or he spends the time to set up classroom management that looks at content management (skills that cut across subjects and activities; cf. instructional management skills, sequencing and integrating additional instructional activities, as well as instruction-related discipline problems [Kounin as cited in Froyen and Iverson 1999, p. 128]), conduct management (inclusion of human diversity into one's instructional philosophy), and covenant management (classroom group and social systems). Research demonstrates that a high incidence of disciplinary problems in the classroom results in a significant impact on effectiveness of teaching and learning. Additional research indicates that strong consistent management and organizational skills lead to fewer classroom discipline problems (Johansen et al. (2011), www.intime.uni.edu/model/teacher/teac3_summary.html). Throughout the years, classroom management has created areas of debate among teachers; however, it is widely recognized that a key component of classroom management is the application and implementation of behavioral approaches.

Sulzer-Azaroff (1981 in Bijou and Ruiz, p. 64) stated the use of behavior modification in the classroom parallels the development of behavior modification in the field of mental health. The majority of early studies conducted in the 1960s focused on the reduction of disruptive behaviors by changing teacher behavior; however, this early application of behavior principles did not teach the students an alternative behavior. Careful consideration of research shared by Birnbrauer et al. (1965), Brigham and Sherman (1968), and Buell, Stoddard, Harris, and Baer (1968) yielded the need to focus on using behavioral procedures to teach students in a way that classroom productivity, language development, and social skills were promoted (Sulzer-Azaroff 1981 in Bijou and Ruiz

1981, pp. 65–67). Subsequent research has contributed to a growing body of research that supports positive classroom management through the use of modeling behavior expectations and differential reinforcement procedures (Sulzer-Azaroff and Mayer 1986). Throughout the years, this research has become more refined and focused on a variety of needs that are represented in the learning characteristics of students with autism spectrum disorders (ASD).

Current Knowledge

The current trends in education emphasize the establishment of positive behavior supports (PBS) and the use of positive behavioral interventions and supports (PBIS) to achieve socially important change (Sugai et al. 2000). The application of positive behavior supports (PBS) and positive behavioral interventions and supports (PBIS) is supported by the US Department of Education and Office of Special Education Programs (OSEP), with an emphasis for schools to use the PBIS framework to impact social, academic, and emotional outcomes for students with disabilities (<https://www.pbis.org>). Although the use of such systems is best practice, students with ASD present unique characteristics within a learning environment. The teacher is challenged to incorporate these unique learning needs into meaningful classroom management and instruction. To do this, the teacher must take into account the needs of the learner in a variety of educational settings. These settings necessitate careful thought about physical structure, instructional management, the student's ability in the areas of communication and social skills and the need to teach the student how to learn under a variety of conditions.

Classroom management for the student with ASD should include consideration of the following aspects of instruction:

1. Physical space in the classroom needs to be set up with clearly defined areas that have visual boundaries (e.g., independent work areas, group work areas, an area for use of technology such as a SMART Board or computer, areas that have critical visual information related to

academic subjects, lighting, noise levels, and the like).

2. Tasks should be presented with clear beginnings and ends – students should be able to recognize when they should start and finish work as well as when they should put away materials (they also need to know where the materials go).
3. Routines should be incorporated into the classroom and flexibility taught and incorporated into plans, that is, program for routine and change.
4. Tasks should be clearly organized, and information should be presented visually.
5. Materials and tasks should be structured and modified so that the student is able to independently respond to the task/lesson.
6. Transitions join tasks together in a natural way – specific transitional elements link tasks together into multitask systems.
7. Communication is used to foster independence – systems are designed so that communication takes place as much as possible without adult presence and dependence.
8. Specific work systems are set up (Montgomery County Public Schools, Services for Students with Autism Spectrum Disorders 2009).

Students with ASD rely heavily on structure and predictable routines, and as such, structure and predictable routines should be incorporated into classroom management. It is key to use these structures and routines consistently and with fidelity. Students with ASD also may need customized visual daily schedules, reduced auditory input, succinct verbal instructions that emphasize key points, consideration of reduced visual distractions (e.g., movement, reflections, background patterns), and consideration of reducing other environmental stimuli that may be incompatible with the sensory sensitivities that are associated with autism spectrum disorders (e.g., temperatures, textures, smells, tastes, the need to move or have movement breaks). The student with ASD will also need to have advance warning about changes in his/her environment; they may need a special place to go to that offers opportunity for relaxation and/or relief from stressful situations that may result from innate anxiety. The student also needs to have contact

with peers who model and offer appropriate social interactions. The teacher should consider the needs of the student with ASD with regard to teaching specific communication and social skills and should structure the environment in a way that promotes these skills within the context of daily routines.

Future Directions

Students with ASD are increasingly present in general education settings and classrooms. As such, teachers need to be aware of their unique learning profiles and ways to incorporate their needs into classroom management. The current movement of the use of positive behavioral intervention systems and school-wide positive behavioral intervention supports is a start in this direction; however, individualization will remain paramount if students with ASD are to have a successful educational experience.

Classroom Structure

Catherine Davies
Indiana Resource Center for Autism Indiana
University, Bloomington, IN, USA

Synonyms

Organization of the physical learning environment

Definition

How the physical environment is organized to facilitate student success in learning (Interactive

Collaborative Autism Network (ICAN) [n.d.](#)). For students with autism spectrum disorders (ASD), classrooms should include a high degree of structure in order to ensure success (Bodfish 2004; Iovannone et al. 2003; Mesibov and Shea 2010). The Structured Teaching approach (an evidence-based approach devised by the TEACCH [Treatment and Education of Autistic and related Communication-handicapped Children] Program in North Carolina, Mesibov & Shea) includes structuring the physical environment (it also incorporates the strategic environment of learning approaches which will not be considered here).

Effective classroom structure for students with ASD should include (Ball [n.d.](#); Mesibov et al. 2004; Mesibov and Shea 2010):

- Physical structure – using furniture to demonstrate expectations and reduce distractions.
- Visual schedules – using objects, pictures, or the written word to show the student the sequence of events.
- Visually structured individual tasks that incorporate object, picture, and/or written instructions.
- Organizing a sequence of individual tasks using visual work/activity systems – using objects, pictures, letters, numbers, or the written word, tasks are organized to show the student what they have to do, how many tasks they need to do, how they are progressing, when they will be finished, and what they are going to do next. For example, lining up the tasks on the students' left and having them move them to their right when completed.

Within these features, the key to student success is that the details of the structure of the classroom are individualized according to the strengths and weaknesses of each student (Mesibov et al. 2004).

Description

The Client Emotional Processing Scale for Autism Spectrum (CEPS-AS) is an observer measure that assesses changes in four emotional processing dimensions: (a) emotion encoding and symbolizing, (b) self-reflective processing, (c) empathy, and (d) mental representation. The CEPS-AS is developed as four subscales, each as a five-point scale designed to be applied to video recordings or transcripts of group psychotherapy. The first subscale consists of five scale stages that define the progression of client involvement along emotion processing continuum that runs from a lack of referent to emotional experience (=scale point 1), through externalized experience (=2), to dysregulation (=3), to internally located and encoding experience (=4), and finally to internal symbolizing and interpersonal awareness of emotion (=5). The second subscale defines the progression of client involvement along the self-reflective processing continuum that runs from descriptive accounts with a scripted quality to self-narrative (=scale point 1), through to a deficit referent to AS self-narrative (=2), to immediate awareness of self that possesses a present quality (=3), to new self-insight with interpersonal awareness (=4), and to finally an introspective referent to self that possesses fluidity and complexity (=5). The third subscale defines the progression of client involvement along the empathy processing continuum that runs from a self-absorbed narrative that lacks any empathic attunement (=scale point 1), through narratives that reflect self as oriented towards others, but where cognitive formulations or empathic conjectures are offered but not synchronized (attuned with the other) (=2), to immediate sharing of affect and resonance through empathic attunement (=3), to accurate sensing of the other with an awareness that they can move and be moved by the other (=4), and finally through to narratives that reflect being mobilized into action as a response to sensing the emotion of the other (=5). The fourth subscale defines the progression of client involvement along the mental representation processing continuum that runs from a narrative which projects own thoughts onto others and discourse that assumes that others have

an awareness of the person's implicit mental representations (=scale point 1), through to an awareness of own and other possessing separate mental representations (=2), to flexibility in manipulating and changing own mental representations (=3), to narrative that reflects an emergence of metacognitive processing of misunderstandings (=4), and finally to narrative that reflects metacognitive thinking in how consideration of own and others' mental representations can occur (=5).

The CEPS-AS is an observer measure and requires raters to be sufficiently trained to identify performance markers in the four dimensions and across experiencing levels. Training skilled autism practitioners to rate performance markers to sufficient levels require a minimum of two training sessions using practice video material to rate. Four-minute video segments are observed and rated. The coding procedure uses partial interval sampling (Bakeman and Gottman 1997) by raters coding the presence ("1") or absence ("0") of behavioral indicators of each of the five ordered levels for each of the four subscales. The scoring procedure uses mean values. The mean indicator value is calculated for each segment. Each 4-min video segment is rated for each client times each dimension ($n \times 4$). The mean indicator values are used for reliability analyses. The interrater reliability is calculated for each individual rater using Pearson r and reliability is calculated for cross-judge averaged data using Cronbach alpha. To calculate session-by-session comparisons of client performances, segments are summarized by averaging first across raters, then across segments within sessions and finally across clients.

Historical Background

The CEPS-AS was developed by psychologists Anna Robinson, PhD, and Robert Elliott, PhD, and published in 2016 by *Journal of Autism and Developmental Disorders*. It was designed to measure emotional processing across group psychotherapy, as observed by therapists and researchers. It was modeled on the Client Experiencing Scale (Klein et al. 1986) and

developed through direct observation of client process during Humanistic Experiential Psychotherapy (HEP). CEPS-AS items were generated from the initial and final video-recall sessions taken from small group Emotion-Focused Therapy with adolescent and adults with Asperger syndrome (AS). Discourse analytic methods were used to identify and describe markers of emotional processing performance resulting in 306 performance markers that were organized within each of the emotional processing domains and codified via an open coding process. The emotion processing domain contained 77 performance markers; the empathy processing domain contained 49 performance markers; the self-reflective processing domain contained 86 performance markers, and the fourth, mental representation processing domain contained 94 performance markers. Using the constant comparative method (Glaser and Strauss 1967) these performance markers were clustered into five graded categories across a continuum of processing in each of the four emotional processing domains.

Following the construction of the CEPS-AS initial validation tests were carried out with two raters. Raters tested video material extracted from two adolescent and adult HEP groups. Raters independently assessed for presence absence of emotional processing performance markers followed by level of performance across the four subscales. Interrater reliability was calculated for both individual raters (Pearson r) reliability and cross-judge averaged data (Cronbach alpha). Preliminary interrater reliabilities of presence absence judgments were quite high for overall ratings averaged across dimensions, with an alpha reliability of 0.84 for judgments combined across the two raters. The alpha reliabilities for ratability judgments on the individual dimensions, for ratings averaged across raters, varied from 0.75 to 0.93, indicating consistently good to excellent interrater reliability.

Psychometric Data

Sensitivity of the CEPS-AS was carried out on the performance markers contained within each of the

four domains. Two raters independently rated 42 four-minute segments of video footage across three periods of treatment: the first regular group therapy session, the first video playback/recall session, and the final video playback/recall session, for both adult and adolescent groups. Each 4-min video segment was rated 12 times (3 clients $\times$ 4 dimensions) by each rater. From the initial trials, CEPS-AS results show interrater reliabilities for processing dimension ratings combined across raters (Cronbach alphas) varied from 0.69 (Emotion Regulation) to 0.91 (Mental Representation); interrater reliability for ratings averaged across the four dimensions was 0.91 indicating good to excellent interrater reliability. However, ratings by single raters (correlations) were somewhat lower, varying from 0.53 (Emotion Regulation) to 0.84 (Mental Representation). Initial findings found a high degree of interrater reliability in identifying the presence or absence of performance markers for the four emotional processing dimensions.

Interdimension correlations were analyzed for both raters (Pearson correlations) across the four processing dimensions. All four dimensions were significantly correlated with each other; this varied from 0.66 ($p < 0.01$; empathy and self-reflection) to 0.82 ($p < 0.01$; self-reflection and mental-representation). The overall interdimension reliability statistic for ratings averaged across dimensions (Cronbach alpha) was 0.91. Preliminary findings show a high degree of overlap, indicating that the four items of the CEPS-AS are not in fact independent dimensions but rather closely interwoven components of emotional processing.

The CEPS-AS was constructed to track emotional processing change across treatment of a group HEP. Sensitivity to change was assessed using repeated measures ANOVA for overall emotional processing and for each of the four processing dimensions. The repeated measure ANOVAs were highly significant for each of the four processing dimensions: Emotion Regulation ($F = 32.70$; $df\ 2,7$; $p = 0.01$); Empathy ($F = 50.45$; $df\ 2,9$; $p = 0.01$); Self-Reflection ($F = 12.83$; $df\ 2,11$; $p = 0.01$); Mental Representation ($F = 34.50$; $df\ 2,12$; $p = 0.01$). The CEPS-

AS demonstrated a moderate to high degree of interrater reliability for discriminating experiential levels across each of these dimensions.

Clinical Uses

CEPS-AS is claimed to be the first reported observer measure for emotional processing using a cognitive-affective self-other dimensional framework. The preliminary findings indicate that the CEPS-AS is sensitive to assessing changes in emotional processing across an intervention aimed at helping participants develop better self-empathy and other empathy at both affective and cognitive levels. In the UK, group social psychoeducation intervention is recommended (National Institute for Health and Care Excellence 2012) for adults with Autism Spectrum Conditions (ASC). Therefore, the CEPS-AS may be a useful clinical tool for therapists to monitor change during group therapy. Measuring changes in empathy in autism uses self-assessment measures, such as the Empathy Quotient (Baron-Cohen and Wheelwright 2004). Preliminary findings from the CEPS-AS indicate potential to discriminate observable changes over the course of treatment. Therefore, CEPS-AS has the potential to be a useful observation tool for clinical trials research on both Humanistic-Experiential Psychotherapies (HEP) and Cognitive Behavior Therapies (CBT). Having an empathy observer measure is a potential useful addition in researching evidence-based practice for group psychotherapies. It will enable researchers to triangulate data with self-assessment empathy instruments.

Although preliminary the CEPS-AS can be viewed as a promising new observer instrument for assessing and tracking client emotion processing and empathy over the course of psychotherapeutic treatment. The initial findings reported high interdimension correlations indicating redundancy among the dimensions requiring further testing to ascertain whether the cognitive-affective components are so closely related that they are not distinct constructs but instead may be overlapping components of the same construct.

Observer measures are time-consuming to carry out and often require significant training of raters therefore reducing the number of items may make the CEPS-AS faster and easier to use. This would be a useful step for clinical use to track changes across treatment.

As a new measure the CEPS-AS research to date is limited. There is the need to evaluate convergent or discriminant validity by assessing empathy self-report (such as, the Empathy Quotient (EQ)), emotion self-report measures (such as the Toronto Alexithymia Scale (TAS-20) Bagby et al. 1994). There is a need to test the validity of the CEPS-AS subscales against performance-based measures such as the Revised Eyes Test (Baron-Cohen et al. 2001). However, initial validation demonstrates the CEPS-AS is sensitive to tracking changes in performance markers in emotion processing regulation, empathy, self-reflection, and mental representation in adolescents and adults with ASC. The CEPS-AS offers a unique observer tool for assessing emotional processing domains across group psychotherapy, as observed by researchers.

Definition

Clinical assessment is the art and science of understanding a person’s behavior using a variety of perspectives (e.g., biological, psychological, and social/cultural) and within the different contexts in which he or she lives. As a science, clinical assessment strives to develop procedures and judgments based upon empirical evidence and

the *critical evaluation of that evidence*. As an art, clinical assessment relies on the creativity and innovation of the clinician to synthesize relevant findings and to develop new theoretical models, new assessment tools, and new applications of existing knowledge and skills beyond the limits of current research yet still be guided by the values, principles, and consensus expert opinion of what constitutes best practice.

Clinical assessment, in general, is always defined within the current historical and cultural context, by the training and credentials of the clinician, and by the purpose of the evaluation. Similarly, clinical assessment of autism spectrum disorder (ASD) is shaped by the current state of knowledge regarding the characteristics of ASD, licensing requirements for clinical practice, and the referral question(s) that will be addressed by the evaluation. The current best practice use of the biopsychosocial model of clinical assessment integrates the most relevant information about the biological, psychological, and social/cultural processes that contribute to a broad and deep understanding of the presenting problem(s). This multifaceted, investigative model also has the greatest potential to identify the most effective targets or “choice points” of timely interventions.

Currently, ASD is primarily defined by specific developmental and behavioral markers (e.g., American Psychiatric Association 2013; World Health Organization 1993). Consequently, the most valid and reliable measures for ASD are, broadly speaking, psychological (i.e., behavioral, developmental, psychoeducational, and neuropsychological) in nature. Medical assessment is usually undertaken to assess the general health of the individual, contributing medical conditions, comorbid medical disorders, and the response to medications known to impact behavior. With the “epidemic” growth in the number of individuals being identified with ASD (e.g., Wing and Potter 2009), greater public and media attention, and advances in biological knowledge and medical technology, there is new promise for significant advances in biomedical applications in the assessment of ASD (Goldstein et al. 2009; Volkmar et al. 2009).

Historical Background

Kanner’s remarkable description of eleven patients in his 1943 English-language article (Kanner 1943) is considered by many to mark the beginning of the modern era of the use of the term *autism* as a formal diagnosis (although it is not clear if Kanner was aware of the concurrent work of Austrian Hans Asperger whose own descriptions of a similar group of patients did not get translated into English until a later date). Professionals working in this area fell into a few categories: those who used the descriptions very broadly, those who used the symptoms to diagnosis very narrowly, those who said autism was part of other childhood disorders, those who said autism was separate from other childhood disorders, and those who used the terms autism and childhood schizophrenia interchangeably (Feinstein 2010). Other researchers started trying to specify observable behaviors and came up with sets of criteria. Over the years, researchers developed their own criteria for what defined autism behaviors, and as a result, criteria used for diagnosis changed.

Confusion with diagnostic labeling, criteria, and exclusionary criteria persisted for many years even as researchers started assembling lists of criteria to be used to diagnose autism. One of the first assessment tools used was a checklist developed by C. G. Polan and B. L. Spencer in 1959 (Feinstein 2010). A list of other early assessment tools can be found in Table 1.

These instruments were the forerunners of modern clinical assessments used for diagnosing ASD. Analyses regarding the psychometric properties of the tools are not discussed in this entry as their inclusion relates to the available tools for that period of time, as well as to show the historical progression. The best diagnostic assessments focus on social and communication challenges (Ozonoff et al. 2005). Current assessment tools have expanded their items to include subtleties associated with people who are on the milder end of the autism spectrum. Today, the field has behavior checklists, screening measures, and diagnostic instruments. Table 2 includes currently

Clinical Assessment, Table 1 Historical look at the assessment for autism spectrum disorders

Name of instrument	Authors	Year published/used	Purpose
Rimland's Diagnostic Checklist for Behavior-Disturbed Children (Form E-1) (published as an appendix in the book <i>Infantile Autism</i>)	Bernard Rimland	1964	Originally a checklist for parents to complete and submit regarding the child's early development, language development, and behavior
Behavior Rating Instrument for Autistic and Atypical Children (BRIAAC)	Bertram Rutterberg, Mitchell Dratman, Julia Fraknoi, and Charles Wenar	1966	An observation and rating system for assessing the behavior of autistic or autistic-like children
A parental questionnaire for the Diagnosis of Infantile Autism	Helen Clancy, Alan Dugdale, and John Rendle-Short	1969	Questionnaire to assist with the identification of autism in childhood. Data gained by using the Creak Committee's criteria from 1961
Handicap Behavior and Skills (HBS)	Lorna Wing and Judith Gould	1978	Designed to gain information on children with mental retardation or psychosis
Autism Behavior Checklist/Autism Screening Instrument for Educational Planning (ASIEP)	David Krug, Joel Arick, and Patricia Almond	1978–1980	Assess, identify, and program for children with autism within an educational setting
Behavior Observation Scale for Autism (BOS)	B.J. Freeman, Edward Ritvo, D. Guthrie, P. Schroth, and J. Ball	1978	Devise a method for analyzing behavior associated with an autism diagnosis, assist with the diagnosis of autism, and assess behavioral changes over time
Psychoeducational Profile (PEP)	Eric Schopler and Robert Reichler	1979	A developmental assessment designed for autistic and psychotic children to provide a profile of the child's strengths and needs
Childhood Autism Rating Scale (CARS)	Eric Schopler, Robert Reichler, Robert DeVellis, and Kenneth Daly	1980	Assist with diagnosis, help distinguish children with autism from children with other disorders, and help determine severity level
Autism Observation Scale	Bryna Siegel, Thomas Anders, Ronald Ciaranello, Bruce Bienenstock, and Helena Kraemer	1986	Developing a classification system for subtypes of children with autism and autistic-like symptoms
Autism Diagnostic Interview (ADI)	Ann Le Couteur, Michael Rutter, Catherine Lord, Patricia Rios, Sarah Robertson, Mary Holdgrafer, and John McLennan	1989	Interview questions for caregivers to assist professionals with diagnosing and distinguishing among the pervasive developmental disorders
Autism Diagnostic Observation Schedule (ADOS)	Catherine Lord, Michael Rutter, Susan Goode, Jacquelyn Heemsbergen, Heather Jordan, Lynn Mawhood, and Eric Schopler	1989	Observe social and communication behaviors and the quality of those behaviors in children with autism and related disorders. Also helps in distinguishing autism and related disorders from non-autistic disorders and typical development

Clinical Assessment, Table 2 Current instruments and interactive tools for assessing autism spectrum disorders

Title	Author(s)	Year published	Purpose
Autism Diagnostic Interview-Revised (ADI-R)	Michael Rutter, Ann Le Couteur, and Catherine Lord	2003	Assists with the diagnosis of autism and helps differentiate between autism and other developmental disorders
Social Communication Questionnaire (SCQ): (two versions) Current Behavior or Lifetime Behavior	Michael Rutter, Anthony Bailey, and Catherine Lord	2003	Based on the ADI-R. Can be used as a screener or to gain diagnostic information
Autism Diagnostic Observation Schedule, Second Edition (ADOS-2)	Catherine Lord, Michael Rutter, Pamela DiLavore, Susan Rissi, Katherine Gotham, and Somer Bishop	2012	Interactive and semi-structured assessment of characteristics related to autism spectrum disorders, particularly social and communication skills
Parent Interview for Autism (PIA), Clinical Version	Wendy Stone, Elaine Coonrod, Stacie Pozdol, and Lauren Turner	2003	Tracks changes in child's characteristics of autism. Can also differentiate autism from other developmental disorders
Psychoeducational Profile, Third Edition (PEP-3)	Eric Schopler, Margaret Lansing, Robert Reichler, and Lee Marcus	2005	Gathers information relevant for a diagnosis, identifies child's strengths and needs, and provides developmental levels
Autism Spectrum Rating Scale (ASRS)	Sam Goldstein and Jack Naglieri	2009	Rating scale assesses behaviors related to ASDs. Completed by parents or teachers. Provides T-scores. Long and short versions are available. Assists with diagnosis, differential diagnosis, and comparing the individual suspected of having an ASD to a normed group
Childhood Autism Rating Scale, Second Edition – Standard Version (CARS2-ST) and High-Functioning Version (CARS2-HF)	Eric Schopler, Mary Van Bourgondien, Janette Wellman, and Steve Love	2010	Expands the original CARS and provides an updated literature review. Added a HF version for individuals suspected of having HFA/AS/PDD-NOS. The standard version is redesigned. Both versions offer T-scores

used tools related to the screening or diagnosis of ASD. Instruments showing psychometric promise or those tools where reviewers have mentioned the need for stronger psychometric properties were not included. As a result, the reader may find reviews of these and other instruments in other sections of the encyclopedia. As the criteria for ASD broaden and even more subtle characteristics are noticed, assessment developers continue looking for ways to assess high-functioning individuals with ASD.

Current Knowledge

General Considerations in the Clinical Assessment of ASD

Although the more classic forms of autism may be accurately and reliably diagnosed by most professionals who have met minimal requirements (in terms of training and experience) in clinical assessment, variation in characteristics across the spectrum, myriad comorbid conditions, and the complex interplay with environmental factors

(e.g., parenting style and family stress) require a higher standard of expertise in order to be proficient in assessing individuals with ASD. The essential impact of autism on an individual, itself, can make traditional methods of clinical assessment inadequate, even when used by otherwise experienced and competent examiners. Anecdotal evidence gathered from years of experience working with individuals on the spectrum suggests that additional considerations may be as important in conducting a robust and meaningful assessment as are the specific techniques or procedures identified in the professional literature.

The first of these additional considerations has to do with the levels of social expectation that are built into most assessment procedures. Of the four methods used in clinical assessment – interview, observation, informal assessment, and the use of norm-referenced and standardized instruments (e.g., Sattler and Hoge 2006) – the direct use of formal tests with individuals being evaluated for ASD requires that the individual has the ability and motivation to tolerate and cooperate in the socially reciprocal activities that define the evaluation experience. The ability to regulate oneself in the presence of an unfamiliar adult, to attend to the spoken and unspoken expectations for appropriate behavior, and to be motivated to perform “to the best of one’s ability” is an example of prosocial behaviors that are typically learned at a very young age but may be underdeveloped in a person with ASD. Consequently, unless compensatory strategies are effectively utilized by the examiner, the result may be a child who is (inappropriately) described as “untestable” (e.g., Schopler and Mesibov 1988). Adding to these test-taking social challenges, the fact that many individuals with ASD may not be able to meet the receptive and expressive language demands inherent in many tests and the likelihood that the individual with ASD may not find his or her narrow interests stimulated by the standard test items, a generic clinical evaluation may assist in confirming an individual’s diagnosis, but the potential for the individual to learn and adapt with individualized supports may be largely unexplored. The key is to have a thorough understanding of how ASD affects an individual’s ability to learn and adapt

and to have a repertoire of assessment and teaching strategies that can be evaluated along with the individual (e.g., Klinger et al. 2009; Shea and Mesibov 2009).

The second consideration is that establishing rapport with the individual with ASD is just as important as it is with someone who does not have ASD, but that the process of developing rapport may need to be more deliberate and require more creativity, and will likely be facilitated with detailed information about the individual’s unique strengths and interests (things to utilize, such as favorite toys or topics) and challenges (things to avoid, such as excessive talking). It is the clinical experience of the authors that examiners with a genuine fondness for working with individuals with ASD and the knowledge, compassion, persistence, and resilience to go along with that passion tend to obtain the most consistently helpful information from clinical evaluations.

And finally, ASD not only impacts the affected individual, but it can have a profound effect on the individual’s family and on those who work with the individual at school or in the community (e.g., Schopler and Mesibov 1984). Indeed, social opportunities, effective communications, and the pursuit of varied interests can all be compromised in a family with a child with special needs. As a result of reallocating precious family resources, the family of a child with ASD can sometimes become more “autistic” itself with reduced social opportunities to attend church or invite neighbors over for dinner, for example, with little time or energy for couples to go on “dates” or to communicate one-on-one, or by eliminating or modifying leisure options (e.g., a family vacation to Disney World) because of challenges the child with ASD might face. Consequently, the various contexts in which the individual with ASD lives and functions need to be assessed and targeted with constructive suggestions. A supportive and collaborative relationship with families (and other care providers, schools, and community agencies) and a clear, honest, and sensitive presentation of the evaluation findings contribute to a better assessment. These factors together can also have the potentially therapeutic benefit of helping parents come to terms with their child’s diagnosis

in ways that help them obtain services, advocate for their child, and assist all family members to cope more effectively (e.g., Mesibov et al. 2005).

Specific Guidelines and Procedures in the Clinical Assessment of ASD

Several excellent resources have emerged in the past 15 years that outline specific guidelines and evidence-informed procedures for conducting clinical assessments of ASD. For students in training or those professionals interested in a refresher course, textbooks on clinical assessment that include a chapter on autistic disorder are available (e.g., Sattler and Hoge 2006). For those individuals or agencies wishing to establish their expertise in this area, specific practice parameters for what constitutes current best practice have been published (Filipek et al. 1999; Volkmar et al. 2014). For those wanting a comprehensive and concise overview of evidence-informed practices and empirically validated measures, well-written articles and books are easily accessible (Kroncke et al. 2016; Ozonoff et al. 2005). And for those looking for a comprehensive discussion of the relevant issues in the assessment of ASD, there are both earlier and recently published options (Goldstein et al. 2009; Schopler and Mesibov 1988). There is a good deal of consensus regarding current best practice, which will be summarized in this section. Interested readers will find additional detail by consulting these resources mentioned previously.

An *individualized assessment plan* is typically organized around (a) identified and latent concerns, (b) the methods used to gather relevant information, (c) the various contexts in which the individual functions, (d) perspectives from parents and multidisciplinary professionals, and (e) the immediate, intermediate, and long-term goals for the individual (see also Cohen 1976). These multidimensional assessments target the *whole* person, including multiple areas of functioning (e.g., academic, communication, and social) to determine relative strengths and weaknesses (e.g., Goldstein et al. 2009; Schopler and Mesibov 1988), thereby allowing for *strength-based* programming. In addition, *emerging skills* are assessed in order to generate treatment or

educational goals that are specific, concrete, and immediate (e.g., Hogan and Marcus 2009). Practically, predetermined assessment protocols and eligibility requirements of service agencies (e.g., Shea and Mesibov 2009), reimbursement schedules of funding sources, and the time, energy, and expertise of the clinician also factor in assessment planning decisions. The most common types of ASD assessments involve determining (a) whether or not an individual should be referred for a more thorough evaluation; (b) relevant diagnosis(es); (c) strengths and weaknesses in information processing, learning, and performance; and (d) the potential for the individual to live and work independently. Each type of assessment establishes an empirically informed best practice basis for addressing the presenting concerns, whether they are, for example, behavioral, academic, or legal. Each of these types of evaluations will be discussed briefly in the following sections. Clinical assessment to weigh the costs/benefits of specific medication trials, or other experimental and sometimes controversial treatments, is beyond the scope of the present discussion.

Screening Evaluation of ASD There are a number of very good publications that discuss relevant issues and available measures for screening young children for developmental delays, in general, and ASD, in particular (e.g., Barton et al. 2012; Filipek et al. 1999; Rogers 2001). Screening procedures can be categorized as somewhat less structured (e.g., interviews, observations, and play-based interactions) and rely on the clinical expertise of the professional, or they may involve a formal procedure requiring a standardized administration and be adapted to both trained and untrained informants. Screening procedures are oftentimes designed to be used by primary and secondary healthcare providers, and they are evaluated based upon how effectively (i.e., sensitivity) they identify children who should be referred to a secondary care agency for a broad assessment of developmental delays (first-level screening) or to a highly specialized tertiary care agency that has expertise in ASD (second-level screening). The Modified Checklist for Autism in Toddlers (M-CHAT), the Quantitative Checklist for Autism

in Toddler (Q-CHAT), the Social Communication Questionnaire (SCQ), the Pervasive Developmental Disorder Screening Test (PDDST), and the Screening Tool for Autism in Toddlers (STAT) are some of the most frequently cited checklists used to screen for ASD (e.g., Norris and Lecavalier 2010; Rogers 2001; Shea and Mesibov 2009). These measures target a range of observable behaviors (e.g., joint attention, responding to one's name, imaginative play, and repetitive behaviors) present or absent in young developing children that indicate a heightened risk for being diagnosed with ASD.

The need for reliable and effective screening procedures for ASD has received heightened attention recently due to the increasing incidence of ASD worldwide and the importance of effective early intervention programs for decreasing the short- and long-term adverse impact of the disorder (e.g., National Research Council 2001). Early screening and early diagnostic assessment are especially active areas of research currently, and there are a number of recently published references in this area (e.g., Barton et al. 2012; Chawarska et al. 2008; Norris and Lecavalier 2010).

Diagnostic Evaluation of ASD The purpose of the diagnostic assessment is to use valid and reliable methods to get meaningful information about how an individual functions and, as appropriate, to assign a diagnostic label to the individual. The diagnostic label signifies a kind and degree of abnormal behavior and development that characterize a subset of a given population. Diagnostic labels are helpful when they can be used to better manage the uncertainty surrounding the individual's behavior and prognosis, enhance communications about the individual, and facilitate access to available resources and effective treatments. Although ASD is generally considered to be a neurodevelopmental disorder, there are currently no biomedical tests or procedures upon which a diagnosis can be made. Information about an individual's early development and current behaviors gathered through interviews with parents and teachers and observations made during structured

and unstructured interactions with the individual form the basis for determining if the individual meets criteria for an ASD diagnosis. Familiarity with normal child development and the broad spectrum of developmental and psychiatric disorders are essential in determining the appropriate diagnosis(es). Inconsistencies in abilities and performance are, by definition, markers for ASD. Especially for the higher-functioning individual, overt symptoms are frequently *context specific*, and a thorough evaluation will gather information from a variety of settings (see also, e.g., Ozonoff et al. 2005). Autism-informed clinical interviews with parents and autism-informed systematic observations of clients during structured and unstructured interactions, when combined with a review of previous medical and educational records, constitute the core components of a diagnostic evaluation for ASD. Currently, the Autism Diagnostic Interview-Revised (ADI-R) and the Autism Diagnostic Observation Schedule (ADOS) (and, presumably, the recently released ADOS-2) are considered by many to reflect the highest standard of evidence-based practice for both clinical and research purposes (e.g., Ozonoff et al. 2005). A medical evaluation and intellectual, communication, and adaptive behavior testing are essential in ruling out other possible explanations or in ruling in comorbid conditions. Information from other cognitive (e.g., neuropsychological) and behavior assessments can also provide useful information that can help clarify a diagnosis (e.g., Goldstein et al. 2009; Ozonoff et al. 2005).

Psychoeducational Evaluation of ASD There is increasing evidence that the structure and function of the brain are different in individuals with ASD, but the precise and essential nature of the differences remains unclear. Even so, these suspected anomalies are presumed to account for the differences in how individuals with autism process sensory information, learn, reason, and perform daily activities. Understanding these unique patterns of information processing and behavior is the primary goal of the psychoeducational/neuropsychological assessment of ASD. As mentioned earlier, obtaining valid and reliable test results is no easy matter when working with

some individuals on the autism spectrum, but it is essential if meaningful goals are to be developed and if effective strategies are to be prescribed. A comprehensive psychoeducational evaluation, broadly speaking, may begin with an assessment of intellectual functioning, communication skills, academic abilities, and social and adaptive behaviors. More sophisticated assessments may target specific areas of cognitive and emotional functioning known to be relative strengths (e.g., rote memory, visual attention and visual/spatial reasoning, routinized learning and performance) or weaknesses (e.g., verbal abilities, novel problem-solving, integrated and applied skills) in individuals with ASD. Although some of these skills can be assessed in individuals with lower abilities, most of the recent developments in this area stem from work with higher-functioning individuals. Both formal and informal measures are being used to assess cognitive abilities such as executive functioning, perspective-taking, central coherence, cognitive flexibility, and social cognition and problem-solving (e.g., Corbett et al. 2009). Subtle language and communication skills assessed may include understanding figurative language and language concepts and pragmatic communication skills (Paul and Wilson 2009). Imaginative and interactive play skills and individual leisure activities are also typically assessed. The goal of a *diagnostic evaluation* is to determine how the individual is *like* others who share a particular diagnostic label. The goal of a *psychoeducational evaluation* is to determine how the individual is *different* than a generic group of individuals (i.e., individual differences). Individualized treatment and an individualized educational plan are only possible when the unique qualities of how the individual relates to him- or herself and to the surrounding environments are understood.

Vocational Evaluation of ASD Recent changes to state and federal guidelines regarding the education of special needs students have resulted in a renewed interest in developing assessment procedures that can facilitate planning for the transition to adulthood. For some individuals on the autism spectrum, this may involve paid or

voluntary work in the community, as well as semi-independent or independent living arrangements. A comprehensive vocational assessment may outline potential areas of employment or community involvement and the supports and strategies that can maximize independent functioning. Structured and meaningful activities, community inclusion, and greater levels of independence often result in the best possible outcome for adults with ASD. A comprehensive vocational assessment focuses not only on vocational skills and interests but on work habits, communication skills, the ability to adapt to different physical environments, and the necessary stress coping, social, and leisure skills that can help determine the level and the supports that will allow the individual to be successfully integrated into the community.

The recently revised TEACCH Transition Assessment Profile (TTAP), Second Edition (formerly known as the Adolescent and Adult Psychoeducational Profile [AAPEP]), is an example of a comprehensive vocational assessment for adolescents and adults with ASD. Although the strengths of its psychometric properties continue to be researched, this assessment tool is a combination of structured interview, observation, and informal assessment techniques designed to be utilized in the natural home, work, and community settings in which the individual lives. Vocational assessments of individuals with ASD seem to demand a greater degree of ecological validity than some of the other measures discussed in this article, and the TTAP appears to have been designed with this in mind.

Future Directions

Clinical assessment is a dynamic process that is shaped by human nature's indefatigable drive to transcend current limits (of knowledge and practice) and to do so in the most efficient way possible. The recent publication of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-V)*, represents the "next step" in our understanding of what constitutes a formal

diagnosis of ASD. As practitioners develop new tools and techniques for assessing individuals with ASD to accommodate the current paradigms and emerging technologies, cutting-edge researchers are already beginning to shape the field's future. Even though this future is difficult to see clearly, there are several trends that are likely to challenge the field in the coming years. For example, children are being evaluated for ASD at increasingly younger ages, some as young as 12 months. Concerned parents and professionals are looking for reliable assessment tools and procedures that can be used with these very young children. In addition, recent advances in identifying biomarkers of ASD during prenatal development and early childhood may eventually translate into clinical practice. Another area for future research involves highly individualized matching of treatment strategies to specific biological, neuropsychological, or behavioral indicators. Currently, there is an active effort to attempt to match children to treatment protocols based upon characteristics of the child (behavioral markers) to optimize outcomes (e.g., Schreibman et al. 2009). Clinical assessment may at some point in the near future work in conjunction with genetic testing and other medical procedures to determine diagnoses and recommended treatment protocols (including targeted genetic and psychotropic interventions). Assessment in the future may increasingly include more widespread use of teleconferencing and digital surveillance (e.g., Schutte et al. 2015). Computer-based assessment tools for caregivers and clients will likely become mainstream. Practitioners will need to stay alert to the trends, best practices, and ethics related to using technology for assessment and diagnosis. An area of future uncertainty involves changing public policy regarding reimbursement and health insurance reform. Redesigned health insurance policies may cover some assessment procedures but not others. This will likely continue to have an indirect impact on the thoroughness and overall quality of an assessment by setting reimbursement rates for services rendered. While practitioners are becoming more skilled at identifying ASD in even

younger children, a subset of older children and adults exists who are not identified until they are much older. As clinicians become more adept at assessing and diagnosing ASD, professionals need to consider the question of whether everyone who is quirky, rigid, different, or eccentric needs a diagnosis. Because of increased media coverage, an increasing number of referrals are being made to specialized clinics by family members and colleagues of individuals who are clearly unusual but who seem to function reasonably well in society without a diagnosis. Adults who learn about ASD through media or personal experience may wonder if they have a diagnosis on the spectrum. Clinicians will need to understand the diagnostic criteria being used, the strengths and limitations of the instruments available, and the presenting problem to best use their professional judgment in making decisions about further assessment.

Clinical Evaluation of Language Fundamentals: Preschool – Second Edition (CELF Preschool-2)

Caitlyn Black, Michelle DeFelice and Rachel Plant

Southern Connecticut State University, New Haven, CT, USA

Synonyms

[CELF Preschool – 2](#)

Description

The *Clinical Evaluation of Language Fundamentals: Preschool 2* (CELF-P 2) assesses all five domains of language: phonology, morphology, syntax, semantics, and pragmatics in children ages 3–6 years. This assessment includes both expressive and receptive modalities, as the child being assessed is expected to produce language and respond appropriately to instructions through spoken and unspoken modes of communication. The CELF-P 2 can be used to identify a language disorder, determine eligibility for services, and identify strengths and weaknesses, all through the use of performance-based tests that have strong relevance and relation to language and developmental milestones. The assessment is presented as a series of levels, 1–4. Level one is designed to determine whether or not a language disorder is present. Level two determines more information about the child's language including modalities used, content understood and expressed, and structures utilized. Level 3 evaluates the child's early classroom and literacy fundamental language, including preliteracy and phonological awareness ratings. Finally, level four determines the child's pragmatic skills in both an educational and home settings.

The CELF-P 2 items are displayed in the format of an easel book, with pictures for the child to reference, or respond to, either by

pointing to the correct option or verbally responding to the examiner's prompt. The time required to administer this assessment varies depending on how many subtests the evaluator chooses to administer. The manual states that it takes around 15–20 min to complete the three main subtests that make up the “core language score” (sentence structure, word structure, and expressive vocabulary). It is suggested that the evaluator begin with these three subtests, as these are used to determine whether a child needs further assessment. If the child's core language score is below the threshold of 85, the evaluator should then continue onto the remaining subtests for further evaluation. The CELF-P 2 materials include stimulus books 1 and 2, a record form, concept and following direction stimulus sheets, preliteracy rating scale, descriptive pragmatics profile, and the examiner's manual. The examiner's manual includes detailed instructions on how to give the assessment, subtests to use, how to score each, and interpret all of the scores.

The CELF-P 2 manual clearly states all aspects related to scoring for the clinician. Each subtest gives information on scoring including allowance of repetitions, discontinue rule also known as the ceiling, and how many points per correct/incorrect answer. The amount of trials ranges greatly between subtests, from 2 trials for Recalling Sentences, to 24 trials each for word structure and phonological awareness. The test then provides norm-referenced scaled scores for the following subtests as follows: sentence structure, word structure, expressive vocab, concepts and following directions, recalling sentences, basic concepts, and word classes. For each of the subtests that translate to scaled scores, the manual instructs the evaluator to take the raw score that has been calculated and then go to the age-appropriate table in Appendix B of the manual to find the corresponding scaled score. The CELF-P 2 scaled scores are based on a mean of 10 and a standard deviation of 3. As previously mentioned, the CELF-P 2 also provides evaluators with the option to do a shorter version, core language score. This shorter version uses three core subtests to assess the child's overall language abilities and

the obtained scaled scores assist in determining the need for further testing.

Historical Background

The first edition of the *Clinical Evaluation of Language Fundamentals: Preschool* (CELF-P) was published in 1992, authored by Elisabeth H. Wiig, Wayne Secord, and Eleanor Semel. The CELF-P was subsequently updated and built upon ultimately creating the CELF-P 2 (2nd edition) with the aim of being a more complete, adaptable, and multifaceted assessment tool for children ages 3–6:11. New developments with the second edition include a variety of changes, including improved psychometric data made up of stronger reliability and validity, and expansion of both the basal and the ceiling for greater diagnostic value within ages 3–4. Additional changes were included to add clarity and efficiency with administration. For example, the manual was revised to improve precision of the examiner directions, and directions are included in stimulus book 1. Lastly, the second edition also broadened the scope of the assessment itself through the inclusion of pragmatics, semantics, and morphosyntax among the test's subject matter. Overall, the improvements to the CELF-P 2 increase the assessment's value, overall application to relevant populations, and appeal to examiners in related fields.

Psychometric Data

The norm-referenced data used for the CELF-P 2 was derived from a sample of 800 children from 3 to 6 years of age. The standard sample elements for the CELF-P 2 are congruous with the demographic data of the 2000 US Census relating to geographical region, sex, race/ethnicity, and caregiver education level. In developing norms, standardization testing included an interruption rule in four subtest areas that were longer than normal (concepts & following directions, recalling sentences, word classes, and recalling sentences in context); allowing as

much item-specific data to be collected as possible without having to administer items beyond the capacity of the child. Using the first edition of CELF-P 2 as well as CELF-4, functions for each subtest were created based on consistency with expectations and growth pattern curves observed.

CELF-P 2 is both reliable and valid. Test-retest reliability for the subtests and composite scores in all ages ranged from 0.78 to 0.94. Internal consistency reliability coefficients ranged from 0.79 to 0.97, thus, indicating that the scores across subtests as acceptable and composite scores as excellent. The prevalence of validity is presented based on assessment content, response process, internal structure, and intercorrelational studies. Correlations between subtests and composite scores were moderate, and additional validation evidence was documented through comparison with other tests of language disorders in children including the CELF preschool, CELF-4, and the PLS-4. These correlations were reported moderate to high which is considered to be good.

Clinical Uses

The CELF-P 2 can be used in a variety of clinical settings to both assess and diagnose and follow-up with children (ages 3–6) who present with language deficits. The CELF-P 2 provides the option to score the child with the “core language score”; thus, the test can be administered effectively and efficiently within a school or daycare setting, in about 15 min. The use of this assessment provides flexibility, allowing the clinician to only administer subtests relevant to the needs of the client. The assessment manual includes a section in which evidence-based studies are referenced. These studies examine the clinical use of the CELF-P 2 to assess special populations such as autism, specific language disorders, and children who are hard of hearing. The assessment manual notes that depending on the type of impairment (motor, sensory, cognitive), the testing environment, and test itself may be adapted to fit the needs of that specific student. Some adaptations provided by the manual include providing

additional cues, increasing the number of demonstrations and trial items, or skipping items that may not be appropriate for that specific child. The manual clarifies that if adaptations are used, the raw score cannot be translated to a scaled score, and the administrator must score the test solely based on the raw scores of the child.

The CELF-P 2 takes into account cultural differences that can affect the outcome of the test. The assessment stresses the importance of evaluating each child in light of their dialect, culture, community, and ethnicity. To avoid cultural bias, the assessment created a panel of seven licensed speech-language pathologists who were known for their expertise in multicultural issues. The team represented expertise in Hispanic, African American, Native American, and Asian cultures, as well as in men's and women's issues. They were tasked with examining the assessment for cultural, ethnic, gender, socioeconomic, and regional bias. Each member of the panel reviewed the subtest tasks, administration procedures, possible child responses, and stimulus pictures for the proposed CELF-P 2. Their feedback was taken into account and discussions about potential issues took place. To ensure that professionals administering the test consider cultural differences, the testing manual includes a section with peer-reviewed data on how culture may affect assessment, as well as word formation rules for dialectal differences. These charts include possible word formation responses for many of the most used dialects. The test also comes in a Spanish form – CELF Preschool-2 Spanish.

Clinical Linguistic and Auditory Milestone Scale

Elizabeth R. Eernisse

Department of Language and Literacy, Cardinal Stritch University, Milwaukee, WI, USA

Synonyms

[Capute scales \(along with cognitive adaptive test\); CAT/CLAMS; CLAMS](#)

Description

The Clinical Linguistic and Auditory Milestone Scale is a 43-item parent questionnaire that is one of two parts of the 100-item Capute Scales. This measure is administered in conjunction with the Cognitive Adaptive Test (CAT), a 57-item assessment of visual-motor functioning. The test uses standardized methods for obtaining information from parent report and from direct interaction between the examiner and the child. The CLAMS utilizes parent report and focuses on expressive and receptive language skills of children up to 3 years of age.

Historical Background

The Clinical Linguistic and Auditory Milestone Scale (CLAMS) was initially developed by

Dr. Arnold J. Capute to screen for language delays in young children between birth and 3 years of age. The initial version of the scale was developed in 1973 (Capute and Biehl 1973), with revisions in 1978 (Capute and Accardo 1978). It was originally developed as a brief screening measure for pediatricians within an office setting. The measure was first normed in 1986 (Capute et al. 1986). A visual-motor scale, the Cognitive Adaptive Test (CAT), was subsequently added to the assessment protocol in order to assist physicians in the differential diagnosis of isolated language difficulties as opposed to global cognitive impairments. This assessment was commonly referred to as the CAT/CLAMS. The CAT/CLAMS was revised and renamed “The Capute Scales,” with the most recent standardization procedures completed in 2000–2001.

Psychometric Data

Various versions of the CLAMS and Capute Scales have been revised and standardized over a period of 30 years. Most recently, in 2004, the Capute Scales were standardized on a multisite sample of 1055 typically developing children that were balanced for sex, age, and race (Visintainer et al. 2004). Results indicated that both measures adequately estimated age-level performance. It is noteworthy that historically the CLAMS has correlated highly with performance on the Bayley Scales of Infant Development (Capute et al. 1986).

Clinical Uses

The Capute Scales were designed as a screening measure for experienced physicians, speech-language pathologists, and occupational therapists in order to allow them to distinguish between global developmental delay and receptive/expressive language problems. It consists of 100 items that are completed in-office using parent report and direct elicitation. Administration time is estimated to be from 6 to 20 min to complete both “streams,”

the Cognitive Adaptive Test (CAT) and the Clinical Linguistic and Auditory Milestone Scale (CLAMS). Forms are available in multiple languages including English, Spanish, and Russian.

Clinical Psychology

Karen Tang

Department of Psychology, University of Notre Dame, Notre Dame, IN, USA
Center for Autism and the Developing Brain, Weill Cornell Medicine, White Plains, NY, USA

Definition

Clinical psychology focuses on the diagnosis and treatment of mental illness, abnormal behavior, and psychological disorders in individuals. In 1907, American psychologist Lightner Witmer first coined the term and defined clinical psychology as the study of individuals through observational or experimental methods to promote change in individuals.

A clinical psychologist has a doctorate (Ph.D. or Psy.D.) in clinical psychology, whereas a psychiatrist has a medical degree (M.D.). A clinical psychologist must be licensed by a state licensing board in order to conduct clinical work as a “clinical psychologist.” A clinical psychologist can be involved in the assessment or treatment of autism spectrum disorder (ASD). In addition, a number of clinical psychologists conduct research on ASD.

Clinical Significance

Domenic V. Cicchetti

Departments of Psychiatry and Biometry, Yale Child Study Center, Yale University, New Haven, CT, USA

Definition

Statistical vs. Clinical Significance: Statistical significance means simply that a result in a given comparison occurs beyond what one would expect by chance alone. Here, and by accepted convention, a comparative result is declared statistically significant if it occurs at or beyond the 5% level. By simple subtraction, this means that there is a 95% possibility that the result did not occur by chance.

The caveat here, and one that many journal editors and even some unenlightened biostatisticians fail to grasp, is that given a large enough number of cases or N, a given comparative result will inevitably occur *beyond chance*, at the 5% level of statistical significance.

In order to guard against this so-called big N phenomenon, enlightened biostatisticians have devised guidelines for defining a result as having reached a level of clinical, as well as statistical significance.

A concrete example, albeit an apocryphal one, can be derived easily from the field of autism spectrum research.

Suppose an inexperienced clinician on a scale of 0–100% agrees with the diagnosis of childhood autism, in 500 cases at 10%. With such a large N of cases, the result turns out to be statistically significant with a chance probability at the scientifically acceptable level of 5%.

Well, any self-respecting autism expert would tell you that 10% chance-corrected agreement, from a clinical perspective, is poor or trivial.

Clinical significance to the rescue comes in the form of a set of clinical criteria developed by Cicchetti and Sparrow (1981) by which:

Size of Reliability Coefficient	Clinical Significance
<0.40	Poor
0.40–0.59	Fair
0.60–0.74	Good
0.75–1.00	Excellent

Earlier, in 1977, Landis & Koch provided the following guidelines for also interpreting the level of clinical or practical significance of chance-corrected inter-examiner agreement levels:

Size of Reliability Coefficient	Level of Clinical Significance
Below 0	Poor
0.0–0.20	Slight
0.21–0.40	Fair
0.41–0.60	Moderate
0.61–0.80	Substantial
0.81–1.00	Almost Perfect

Similarly, Fleiss (1981) and Fleiss et al. (2003) also suggested conceptually similar guidelines by which:

Size of Reliability Coefficient	Level of Clinical Significance
<0.40	Poor
0.40–0.75	Fair to Good agreement
Above 0.75	Excellent agreement

Finally, conceptually similar guidelines ranging from, say, Poor to Excellent or Trivial to Very Large, have been developed for correlations of various types, and for judging the internal consistency level of assessment instruments (e.g., Cicchetti 1994).

Clinical Social Worker

Lisa Castagnola
Child Study Center, The Edward Zigler Center in Child Development and Social Policy, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Clinician](#); [Mental health practitioner](#); [Therapist](#)

Definition

Social work is a broad field with a wide range of variation in areas of professional practice. Clinical social workers are social work professionals who provide direct services to client populations. This is in contrast to non-clinically based social workers who may practice in the realm of social administration or who may be more focused on broad-based advocacy and policy reform at the national, state, and community levels. Clinical social workers strive to improve the quality of life and advocate for clients on a more individual level. The term clinical social worker is most closely associated with social workers who provide direct mental health and behavioral health services. These therapeutic services are provided in a variety of settings including hospitals, community mental health clinics, schools, residential facilities, and correctional facilities. Clinical

social workers provide services for a variety of populations that cover the entire life span including children, adolescents, adults, and the elderly and intervene by working directly with individuals, couples, families, and groups (Hepworth et al. 2006, p. 25).

Clinical social workers are knowledgeable on a wide variety of mental health disorders and are well versed and qualified to conduct mental health assessments, render diagnoses, develop treatment plans, and provide short- and long-term treatment. In comparison to other trained mental health professionals, the social work approach gives special attention to the client's stated goals and incorporates these goals into treatment while also taking into account client's functioning within his or her environment. Additional social work values include high regard for dignity and worth of client, upholding human rights, and respect for diversity (Hepworth et al. 2006, pp. 8–11).

Clinical social workers are the largest group of mental health providers in the United States (Manderscheid and Henderson 2001). As such, clinical social workers are often direct service providers to children and adults with autism spectrum disorders (ASD). Due to being employed in a variety of settings, social workers are often among the first healthcare providers to identify signs and symptoms of developmental delays in children. Additionally, multi-disciplinary ASD assessment team models may include a clinical social worker. Following an ASD diagnosis, clinically trained social workers provide support and education to families, assist in implementing behavioral interventions, and link clients to additional services and resources. Social workers also play a key role as advocates for clients with ASD within a variety of community systems.

Professional social workers typically have a Master of Social Work (MSW) degree. Most MSW programs are accredited by the Council on Social Work Education (CSWE) and require a substantial number of direct practice hours as an intern under close supervision. All social workers must complete a significant number of supervised direct practice hours beyond their degree program

to qualify for advanced licensure. Distinction of advanced practice is commonly noted as Licensed Clinical Social Worker (LCSW) or Licensed Independent Social Worker (LISW). All professional social workers are trained and expected to practice within the Social Work Code of Ethics as established by the National Association of Social Workers (NASW).

Clock Drawing

Lauren Schmitt
 Psychiatry, UT Southwestern Medical Center,
 Dallas, TX, USA

Synonyms

[CDT](#); [Clock-drawing test](#)

Definition

The clock drawing test (CDT) is a neuropsychological assessment tool completed with pencil-and-paper that examines executive functioning, motor planning, and visuospatial skills. The test typically consists of two phases: command and copy. In the command phase, subjects are asked to draw the face of a clock and add hands to indicate a specific time (usually 10 past 11). In the copy phase, subjects are asked to copy a pre-drawn clock. Performance on the test is assessed by determining whether the hand-drawn clock meets certain criteria. Administrators may score the clock according to the following: number inclusions and location, spacing, organization, and correctness of hand position. Although the above instructions and scaled scoring system are commonly used, there is no standardized method of administration or scoring. Performance errors in the CDT are indicative of impairment in executive functioning.

This test is used in neurological and psychiatric patient populations, most commonly completed with at-risk dementia and Alzheimer's patients. It is sometimes used as a part of a neuropsychological assessment for children with Autism Spectrum Disorder.

⁵Lurie Center for Autism, Massachusetts General Hospital, Lexington, MA, USA

⁶Nancy Lurie Marks Professorship in the Field of Autism, Harvard Medical School, Boston, MA, USA

Synonyms

3-Chloro-5-[3-(dimethylamino)propyl]-10,11-dihydro-5H-dibenz[*b,f*]azepine monohydrochloride; Anafranil; Clomipramine (CMI) hydrochloride

Indications

Clomipramine is a tricyclic antidepressant (TCA). TCAs block the reuptake of serotonin and norepinephrine in the neuronal synapse, resulting in increased concentrations of both neurotransmitters. This is the mechanism by which it is thought that TCAs exert their therapeutic effects. In the United States, clomipramine is FDA-approved for the treatment of obsessive-compulsive disorder (OCD) in children, adolescents, and adults. Behind selective serotonin reuptake inhibitors (SSRIs), clomipramine is among the drugs of

choice for the treatment of OCD (Stahl 2008, 2009). It is also often prescribed for depression (including severe and treatment-resistant depression), cataplexy syndrome, anxiety, insomnia, and neuropathic or chronic pain, although it is not FDA-approved for any of these disorders (Stahl 2009). Unfortunately, its adverse effect profile has limited its use in many patients.

Mechanisms of Action

The exact mechanisms of action are unknown for the tricyclic antidepressants (TCAs) including clomipramine. However, likely mechanisms of action are suggested from the binding activity and receptor affinities of the active compounds of these drugs and from what is known about the pathophysiology of the disorder being treated. Dysregulation of serotonin and dopamine or both is thought to be implicated in OCD. Clomipramine is thought to alleviate obsessions and compulsions in OCD through its inhibition of the reuptake of serotonin in the brain. Its strongest neurological action is its activity as a serotonin reuptake inhibitor (SRI), and it has been described as being “a relatively selective [SRI]” (Andreasen and Black 2001a, “Somatic Treatments,” p. 721).

The SRI action of TCAs causes an increase in the amount of synaptic serotonin. Before the neurons are desensitized to the drug, this increase in synaptic serotonin is counteracted by its stimulation of the presynaptic serotonin autoreceptor which inhibits the further release of serotonin into the synapse. After about 10–14 days of drug treatment, this autoreceptor is desensitized, and the amount of synaptic serotonin increases. TCAs also increase the activity of postsynaptic serotonin_{1A} receptors and downregulate serotonin₂ receptors further augmenting the effects of the serotonin.

The active metabolite of clomipramine, desmethylclomipramine, is not an SRI but inhibits the reuptake of norepinephrine. This norepinephrine reuptake inhibition is thought to increase the effects of norepinephrine by increasing the amount of norepinephrine in the synapse by blocking the reuptake of norepinephrine. Before

the neurons are desensitized to the drug, this increase in synaptic norepinephrine is counteracted by its stimulation of the presynaptic α_2 -adrenergic autoreceptor which inhibits the further release of norepinephrine into the synapse. After this autoreceptor is desensitized, the amount of synaptic norepinephrine increases. Although the postsynaptic norepinephrine receptor is down-regulated by the increase in the amount of synaptic norepinephrine, this effect seems less significant than the increase in synaptic norepinephrine. However, no known connection exists between the inhibition of the reuptake of norepinephrine by desmethylclomipramine and the treatment of OCD.

Specific Compounds and Properties

Clomipramine has the International Union of Pure and Applied Chemistry (IUPAC) name 3-chloro-5-[3-(dimethylamino)propyl]-10,11-dihydro-5-*H*-dibenz[*b,f*]azepine monohydrochloride and the chemical formula $C_{19}H_{23}ClN_2 \cdot HCl$. The chemical structure of clomipramine only differs from that of the TCA imipramine in that clomipramine has an additional chloride atom. Pure clomipramine hydrochloride is a solid, white crystalline powder at room temperature and is soluble in the polar solvents water, methanol, and methylene chloride but not in the non-polar solvents ethyl ether and hexanes (Fig. 1).

Clomipramine, Fig. 1 Chemical structure of clomipramine

Clomipramine is metabolized by the liver via undergoing N-demethylation of clomipramine to the active metabolite desmethylclomipramine and subsequently by N-oxidation and aromatic hydroxylation. These processes are catalyzed by the enzymes CYP 1A2, 2C19, and 3A3/4, and CYP 2D6 (clomipramine and desmethylclomipramine), respectively. Aromatic hydroxylation is important for the elimination of the drug in the body.

In plasma, clomipramine has a half-life of 15–60 h, a clearance of 20–120 Liters per hour (L/h), and a therapeutic dose range of 150–300 mg per day (mg/day). This drug has a therapeutic plasma level of greater than 150 nanograms (ng) of clomipramine and desmethylclomipramine per milliliter (mL). The main pharmacological action of the TCAs with tertiary amines on their side chains, including clomipramine, is to inhibit the reuptake of serotonin, although it also downregulates serotonin receptors. Clomipramine is the strongest SRI of the TCAs. TCAs with a tertiary amine structure on the side chain of the molecule, such as is the case with clomipramine, have shown less tolerability than those with secondary amines on the side chains (Fig. 2).

Desmethylclomipramine is metabolized by the liver, leading to the elimination of the drug in the body. The main pharmacological action of the TCAs with secondary amines on their side chains, including desmethylclomipramine, is to inhibit the reuptake of norepinephrine.

Clomipramine, Fig. 2 Chemical structure of desmethylclomipramine, active metabolite of clomipramine

Clinical Use (Including Side Effects)

The brand-name drug Anafranil has been FDA-approved for the treatment of obsessions and compulsions in individuals with OCD since 1989. Its active ingredient clomipramine is currently used for the treatment of depression in Europe. Clomipramine has also been shown to be effective in studies to treat hyperactivity in children with autistic disorder and attention deficit hyperactivity disorder (ADHD) and to treat the symptoms of panic disorder, Tourette's syndrome, cataplexy, and body dysmorphic disorder. This drug has also been found to be effective in preventing relapse of anorexia nervosa. Additionally, preliminary studies of the use of TCAs such as clomipramine for the treatment of trichotillomania have suggested at least some efficacy regarding reducing hair-pulling behavior, but controlled studies have yet to be undertaken. Reports have indicated that clomipramine may also be used to treat depersonalization disorder. Clomipramine may be used to treat self-injurious and stereotypic movements in stereotypic movement disorder.

Clomipramine is not currently approved for the treatment of autism or other autism spectrum disorders (ASDs), but researchers have studied its effectiveness in treating symptoms associated with ASDs, particularly autistic disorder. Gordon et al. (1992) found that clomipramine was more efficacious than desipramine and placebo on ratings of autism and anger, as well as repetitive or compulsive behaviors, in children with autism aged 6–18 years. Gordon et al. (1993) found that clomipramine was more efficacious than desipramine and placebo in children with autism with regard to stereotypies, anger, and compulsive, ritualized behavior. It was also superior to placebo in managing hyperactivity. In an open-label trial looking in adults with ASDs, Brodtkin et al. (1997) found that clomipramine may be effective at reducing repetitive thoughts and actions and aggressive behavior and for improving eye contact and verbal responsiveness. In another open-label trial looking at hospitalized children aged 3.5–8.7 years with autistic disorder, Sanchez et al. (1996) found clomipramine to not be therapeutic and posited that young autistic children

may be more prone to experiencing unwanted side effects compared to older patients. Remington et al. (2001) compared clomipramine to haloperidol and placebo in patients with autistic disorder aged 10–36 years and found that clomipramine was comparable to haloperidol in terms of improvement in maladaptive symptoms. Haloperidol was better tolerated than clomipramine. Hazell (2007) reviewed the literature looking at available treatments for attention deficit hyperactivity disorder (ADHD) symptoms in autistic disorder and found clomipramine to be of unlikely benefit.

A typical starting dose in adults is 25–75 mg per day (mg/day) of clomipramine. The dose is titrated up by 75 mg/day each week to the therapeutic dose range of 150–300 mg/day. In children, demethylation of clomipramine to desmethylclomipramine is faster than in adults; as a result, children require higher doses of medication per kilogram (kg) of body weight than do adults since desmethylclomipramine lacks the serotonin reuptake activity of clomipramine. An effective dose for children is generally 2.5–3.5 mg clomipramine/kg body weight. When puberty begins in a child taking clomipramine, the dose can be decreased by up to half of the previous dose. To discontinue a TCA, the drug must be tapered. Clomipramine can be tapered by 25 mg every 2–3 days. Relapse may occur upon discontinuation. The abrupt discontinuation of a dose within the therapeutic range of a TCA may induce cholinergic rebound syndrome, and cases have been reported of rebound manic or hypomanic episodes upon abrupt discontinuation of a TCA.

TCAs become toxic at concentrations greater than 450 ng/mL. Overdose may result in any of the following: agitation, confusion, convulsions, hypotension, tachycardia, cardiac conduction delays, anticholinergic blockade, bowel and bladder paralysis, disturbed temperature regulation, mydriasis (abnormal pupil dilation), and delirium. A TCA overdose may induce a coma, sometimes with shock and respiratory depression, which typically lasts less than 1 day. Patients at risk for making a suicide attempt should be given weekly, nonrefillable prescriptions of their TCAs. Risks include suicidal ideation or increased depression

in individuals with major depressive disorder (MDD), decreased blood pressure, and tachycardia. Adverse effects may include seizure, tremor, sedation, fatigue, dry mouth, dizziness, somnolence, constipation, nausea, increased sweating, impairment of memory, delirium, cardiac arrhythmias, cardiac arrest, headache, abnormal vision, anorexia, dyspepsia, insomnia, orthostasis, sexual dysfunction, weight gain, and anticholinergic effects.

Clomipramine (CMI) Hydrochloride

► Clomipramine

Clonazepam: Definition

Karthikeyan Aradhanareeswaran
Autism Program, Child Study Center, Yale School of Medicine, New Haven, CT, USA
Program in Neurodevelopment and Regeneration, Yale School of Medicine, New Haven, CT, USA
Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, USA

Synonyms

Clonotril; Klonopin; Linotril; Rivotril

Definition

Clonazepam is a benzodiazepine and a positive allosteric modulator of the GABA_A receptor. Instead of opening the GABA_A receptor chloride channel in the absence of GABA binding, benzodiazepines, like clonazepam, accentuates GABA signaling upon GABA binding to the GABA_A receptor. GABA, or gamma-aminobutyric acid,

is the primary inhibitory neurotransmitter in the mature mammalian CNS, with glutamate being the primary excitatory neurotransmitter. The excitatory/inhibitory neuron imbalance hypothesis of the underlying neurobiology of autism is a highly prominent and well-evidenced one. ASD patients frequently show increased levels of glutamate and excitatory signaling. So, correspondingly increasing levels of GABA, the inhibitory neurotransmitter, should have the potential to reverse some ASD symptoms. However, while the premise of using benzodiazepines is theoretically well-founded, there is little to no evidence of their actual effectiveness in human ASD patients. Clonazepam is able to reverse autistic-like symptoms that accompany Dravet syndrome, a rare epilepsy disorder, in a mouse model. Currently, clonazepam is used to treat panic disorder, anxiety, and seizures. Side effects include sedation, dizziness, loss of orientation, sleep disturbances, and weakness.

Definition

Clonidine is an α -2 agonist, typically used as a medication in patients with ASD to target symptoms related to attention, hyperactivity, anxiety, or sleep. It has no FDA-specific indications for this population but is approved for treatment of ADHD in ages 6–17, and is available in multiple preparations including oral and transdermal. Therapeutic effects are thought to be mediated through α -adrenoreceptors that cause a reduction in sympathetic nervous system tone and vital signs such as blood pressure and heart rate. Common side effects include somnolence, dry mouth, constipation, and dizziness. Due to potential effects on blood pressure or heart rate, initiation or discontinuation of this medication should be managed closely by a physician. Studies investigating clonidine in patients with ASD are not robust, with only two small placebo-controlled double-blind trials published that showed some benefit for ADHD/hyperarousal symptoms and irritability (Frankhauser et al. 1992, Jaselskis et al. 1992). Most recently, a retrospective study by Ming et al. (2008) found clonidine to benefit individuals with poor sleep, aggression, mood instability, and

ADHD symptoms. Despite this lack of published evidence in the ASD population, clonidine is commonly used in clinical practice with perceived good therapeutic effect.

Definition

Clozapine is an atypical antipsychotic that is FDA-approved for the management of treatment-resistant schizophrenia. It is believed to antagonize dopamine-2 (D₂) receptors, which causes reduced symptoms of psychosis and stabilizes affective symptoms, as well as serotonin 2A (5-HT_{2A}) receptors, causing enhanced dopamine release in certain brain regions and possibly improving cognitive and affective symptoms (Stahl 2009). However, its pharmacological profile is highly complex and likely involves multiple pathways yet to be uncovered.

Clozapine is typically reserved for patients who have not responded to other antipsychotic medications or who have suffered unwanted side effects from such therapies, such as tardive dyskinesia or extrapyramidal symptoms (EPS) (Novartis 2010). Clozapine rarely causes tardive dyskinesia and is even known to reduce dyskinesias and EPS, like dystonia (Saddock and Saddock 2007). It is the only antipsychotic that has demonstrated a reduced risk of suicidal behavior in patients with schizophrenia and schizoaffective disorder (Novartis 2010). For many of these reasons, clozapine is considered the “gold standard” in the treatment of

schizophrenia and schizoaffective disorder, but its use is limited by its side effect profile. A potentially fatal adverse effect is agranulocytosis, characterized by a decreased white blood cell count ($WBC < 2,000/mm^3$) and experienced in 1–2% of patients who take clozapine after 1 year of treatment. Every patient undergoing clozapine treatment receives weekly blood draws for 6 months, followed by biweekly blood draws for an additional 6 months, to monitor for agranulocytosis. This can be a cumbersome and painful process, which is why clozapine is often reserved for those who have had minimal success with other medications. Other adverse effects include an increased risk of seizures, excessive salivation, weight gain, cardiometabolic risk, and myocarditis (Stahl 2008).

Clozapine is not currently approved for treatment of autism spectrum disorders (ASDs). There have been, however, four case reports of clozapine use in the treatment of individuals with autistic disorder (autism). These reports described clozapine use in a 32-year-old autistic male (Gobbi and Pulvirenti 2001), three autistic children ranging in age from 8 to 12 years (Zuddas et al. 1996), a 17-year-old autistic adolescent male with mental retardation (Chen et al. 2001), and a 15-year-old autistic female (Lambrey et al. 2010). Overall, these reports suggested favorable improvement in some symptoms, particularly aggressiveness. Double-blind, placebo-controlled data is needed before recommendations can be made regarding the efficacy of clozapine use in treating ASDs. Clinical benefit must be heavily weighed against clozapine's extensive side effect profile before starting it in any patient.

Cluster Analysis

Vicki Bitsika

Faculty of Humanities and Social Sciences, Bond University, Robina, QLD, Australia

Definition

Cluster analysis is a statistical technique which seeks to group individuals according to their similar characteristics. That is, “clusters” of characteristics which might, for example, group individuals who make pottery would include fine motor skill, eye-hand coordination, sensitive

tactile receptors in fingers and hands, high level of ability to perceive moisture content in earth materials, and good color discrimination. While not all individuals with one or two of these characteristics will be able to become a good potter with appropriate training, people who possess all or most of these features will have a distinct advantage in becoming talented potters. Similarly, individuals who exhibit the cluster of symptoms associated with an Autism Spectrum Disorder will be more likely to actually have this condition. However, because there is substantial variation in symptom expression between individuals with particular autism disorders, there has been some conjecture as to what comprises Autistic Disorder versus Aspergers Syndrome or Pervasive Developmental Disorder-Not Otherwise Specified. Cluster analysis allows for identification of clinical subgroups (based on the type, number of, and severity of symptoms) to facilitate recommendations for appropriate treatment – especially early in life when specialized intervention has the potential to result in the greatest positive outcomes for the individual.

Historical Background

The evolution of conceptualizations of autism and reflection of these in the major diagnostic manuals is important in understanding the barriers to accurate diagnosis of those individuals who either do not fit a predetermined diagnostic profile due to subtle expression of symptoms or who present with a complex combination of impairments impacted by comorbid disorders. The transition of autism from an all-or-none condition with one fixed constellation of symptoms to a *spectrum* representing substantial variation in symptom expression has been significant in shaping clinicians' utilization of diagnostic criteria for the purpose of accurate identification. This transition is best exemplified in the changes to diagnostic categories shown in the Diagnostic and Statistical Manual (DSM manual) from its initial publication in 1952 to the 5th edition due for release in 2013. Since the DSM has remained prominent in formal

decisions regarding the standards for diagnosis of autism conditions, the evolution in autism conceptualizations will be examined in relation to DSM adaptations to those standards over time.

Despite its robust history in the clinical research since 1943, autism was not recognized as a distinct disorder of childhood in the DSM until its third edition (DSM-III: APA 1980). The DSM-III conceptualized autism as an all-or-none condition by presenting one diagnostic category (i.e., Infantile Autism) and six diagnostic criteria with the stipulation that evidence of impaired functioning was required for all six of these for a diagnosis of autism to be made. This basis for classification was criticized as being limited because it focused only on those cases in which neurological impairment was evident at birth. Children who exhibited regression in functioning between the ages of 18 and 36 months were not clearly represented, thus leading to subsequent revision of the Infantile Autism category to Autistic Disorder in 1987 with publication of the DSM-III-R. This new diagnostic label acknowledged the possible presence of two autism subtypes (i.e., Infantile Autism and Regressive Autism) distinguished on the basis of the age at which children displayed the pattern of impairments indicative of neurological abnormality.

The DSM-IV (APA 1994) and its revision, the DSM-IV-TR (APA 2000), offered a broader diagnostic framework which allowed for identification of high functioning individuals with average to above average cognitive ability and reasonably well-developed language skills. In addition to specifying five subtypes of Pervasive Developmental Disorder (i.e., Autistic Disorder, Aspergers Disorder, Rett's Disorder, Childhood Disintegrative Disorder, and Pervasive Developmental Disorder-Not Otherwise Specified), there was revision of the diagnostic criteria to encompass a wider range of atypical behaviors and reduce the number of symptoms required for a formal diagnosis. In the case of Autistic Disorder, the DSM-IV-TR (APA 2000) maintained the "triad of impairment" model (Wing and Gould 1979) with stipulation that qualitative discrepancies, between the child and chronologically

similar peers, should occur in *social interaction* (at least two of four symptom clusters) and *communication* (at least one of four symptom clusters), along with presence of *restricted, repetitive, and stereotyped patterns of behavior, interests, and activities* (at least one of four symptoms clusters). Despite this expansion of diagnostic categories, clinical researchers (e.g., Lord and Risi 2000; Schuler and Fletcher 2002; Tidmarsh and Volkmar 2003) continued to argue that the variability in manifestation of symptoms from one individual to another was not adequately addressed by the DSM-IV-TR (APA 2000), thus risking poor identification of high functioning individuals. Also, strict adherence to the “triad of impairment” model did not acknowledge the full constellation of difficulties (e.g., hypersensitivity to sensory stimuli in the environment, restricted diet, and poor sleeping patterns) of clinical significance in understanding the issues which disrupted daily functioning and would require specialized intervention (Keane 2004; Lord and Risi 2000). The latest version of the DSM, currently in draft form, contains some evidence of attempts to encompass a broader range of functional levels in autism and these attempts will be further discussed.

Current Knowledge

The term Autism Spectrum Disorder (ASD), first introduced by Lorna Wing in 1992, has replaced Pervasive Developmental Disorder as the collective label for Autistic Disorder, Aspergers Disorder, Pervasive Developmental Disorder-Not Otherwise Specified, and Childhood Disintegrative Disorder with this last condition being an addition to the group of diagnoses represented by the ASD label. It is also proposed that the three impairment domains listed in earlier editions of the DSM be reduced by merging the communication and social behavior categories (Criterion 1) on the basis that symptoms in these domains are interrelated and possibly due to similar contextual antecedents. In addition, it is argued that atypical communication is not exclusive to autistic disorder nor is it significant to functional impairment in

all cases, thus leading to its re-conception as a contributing rather than defining aspect of ASD. Further, Criterion 1 requires evidence of developmental delay in all three areas of social/communication functioning which include deficits in: social-emotional reciprocity, nonverbal communication, and capacity to maintain relationships. The second diagnostic criterion pertains to presence of fixated interests and repetitive behaviors with stipulation that atypical performance be recorded for two of four symptom clusters: (1) stereotyped or repetitive speech, motor movements, or use of objects; (2) excessive adherence to routines; (3) restricted interests of abnormal intensity; and (4) hyper- or hypo-reactivity to sensory input or unusual interest in sensory aspects of the environment. Interestingly, the DSM-V draft includes a diagnostic criterion which states that symptoms might not become evident until the child is exposed to social stimuli which create demand (s)he is incapable of responding to due to underlying skill deficits. This inclusion in the DSM-V draft provides a basis for continued monitoring of cases with suspected ASD to ensure they are accurately identified and provided with access to specialized educational support at the earliest possible time.

Notwithstanding these potentially advantageous revisions to diagnostic criteria, alternations such as amalgamation of diagnostic categories and removal of Aspergers Disorder as a distinct diagnostic label have created controversy in the clinical field. Further, the anticipated elucidation in methods for identification of complex cases and those with more subtle symptom manifestation has not been realized. Marttila et al. (2011) applied the draft DSM-V diagnostic criteria for ASD to evaluate 26 children with an autism condition confirmed by their Autism Diagnostic Interview-Revised (ADI-R) and Autistic Diagnostic Observation Schedule (ADOS) scores. Those researchers reported that DSM-IV criteria were not of sufficient sensitivity to identify high functioning children with well-developed communication skills and paucity of stereotyped and repetitive behavior. Findings such as these emphasize that the heterogeneity which exists in the autism spectrum cannot be adequately accounted

for by diagnostic categories requiring a fixed profile of symptoms for formal diagnosis. Witwer and Lecavalier (2008) report that there is significant variation in symptom manifestation within DSM diagnostic categories and argue for greater investigation of alternative approaches to categorization.

Cluster analysis shows promise as a system for clarifying differences in functioning across the autism spectrum by leading to identification of subgroups which are potentially independent of diagnostic labels. Cluster analytic investigations of the past decade have focused on detection of those dimensions (arising from skill deficits) most capable of providing a valid basis for differentiating between groups of individuals with an autism condition. While the spectrum concept of autism argues that there is an underlying dimension or set of dimensions along which all individuals will vary, there is still debate over precisely what constitutes this underlying dimension (Szatmari 1992). A large proportion of studies have examined whether impairment in particular aspects of functioning (e.g., cognitive vs. adaptive behavior) or combinations of deficits (e.g., cognitive plus social skill) represent a reliable basis for forming homogeneous autism subgroups. Other studies have sought to examine whether number of symptoms or severity of deficits might result in accurate differentiation to allow for a more inclusive basis for understanding and treating individuals on the autism spectrum.

Eaves et al. (1994) reported on a cluster analysis which grouped children into four subtypes based on number of symptoms and extent of cognitive impairment. Groups were described as representing typical autism (autistic disorder), low functioning autism (intellectually impaired), high functioning autism (Aspergers disorder), and “hard to diagnose” with mild to moderate cognitive disability and a family history of learning difficulties. Researchers such as Prior et al. (1998) have indicated that the distinguishing feature between autism subgroups is related to the severity of social and cognitive impairments rather than distinctive symptom patterns. That study supported the concept of a spectrum of autistic dysfunction which places children on a

continuum from low functioning to high functioning. The concept of a spectrum was previously supported by Sevin et al. (1995) who suggested that the *degree* of impairment in the core features of autism (i.e., social interaction, language and communication, and restricted and ritualistic behaviors) is the most important basis for making sense of the variety of behaviors which fall under the umbrella of autism. Fernell et al. (2010) also argued for the significance of symptom severity in clarifying the variations in functioning which characterize individuals with an autism disorder. Those researchers presented a seven-cluster model of subgroups of preschool children who were differentiated on the basis of cognition, behavior, speech and language, and motor control. Similarly, Wiggins et al. (2009) presented a three-cluster solution for 186 toddlers who fell into homogeneous groups due to variation in social/communication and cognitive skills plus the rate and intensity of repetitive behavior and presence of abnormal sensory responding. Lane et al. (2010) and Lane et al. (2011) used model-based cluster analysis of parent reports of their children’s sensory responses to explore the presence of subgroups differentiated on the basis of type of sensory processing dysfunction. Those researchers identified three sensory subtypes (i.e., sensory-based inattentive seeking, sensory modulation with movement sensitivity, and sensory modulation with taste/smell sensitivity) and argued that these subtypes would have a differential impact on core autism symptoms as well as requiring different remediation strategies. Verte et al. (2006) examined the question of whether children with autism disorder could be differentiated into subgroups based primarily on their scores from the Children’s Communication Checklist and reported a three-cluster solution in which differentiation was achieved in relation to severity of communication deficits such as inappropriate initiation, stereotyped conversation, and interactional rapport. Studies such as this indicate that it is variation in the social-pragmatic aspects of language which allows for separation of individuals into clinical subgroups rather than verbal ability per se. The significance of using language performance to assist in establishing specific

subgroups of individuals has been previously discussed by Tager-Flusberg and Joseph (2003). In both studies, level of cognitive disability was found to mediate the effects of language impairment.

Future Directions

Manualized diagnostic systems, although necessary for standardization of decisions regarding the presence of autism, have not represented all aspects of the spectrum well. The DSM-V draft, despite its proposed revisions in the diagnostic categories for autism disorder, does not appear to offer substantial improvement in accounting for the full range of phenotypes which present in the clinical environment (Marttila et al. 2011). This limitation is exacerbated by the clinical finding that individuals with the same diagnosis can and do exhibit varying profiles of impairment and behavioral disturbance, thus leading to heterogeneity within diagnostic groups (Witwer and Lecavalier 2008). Clinical issues such as these bring into question the common practice of using a diagnostic label as the basis for intervention planning. This label-driven intervention approach, which guides clinicians in the field to apply genetic strategies designed to *remediate aspects of autism*, has not resulted in strong positive outcomes and prompted the call for additional analyses to elucidate specific autism subgroups that can be treated more directly (Bitsika 2008; Perry et al. 2009).

Identification and description of clinical subgroups via statistical methods such as cluster analysis can contribute to development of targeted interventions capable of building competencies to enhance positive outcomes for individuals with an autism disorder in the long term. There are a number of considerations which might be of merit in maximizing the contribution of cluster analysis to effective treatment. Traditionally, studies in this field have relied on total scores from standardized tests (e.g., WISC Full Scale IQ) to establish clinical subgroups which share the same characteristics on specified dimensions

(e.g., social skill and communication). It is suggested that future research elaborates on standardized data via inclusion of subtest scores to facilitate an in-depth investigation of specific abilities. Although differentiation of individuals with autism disorder on the basis of global abilities such as intelligence and adaptive behavior has been useful in more precise classification, it is their behavioral challenges which are particularly disruptive to social functioning and often the reason for referrals for intervention. Researchers (e.g., Bitsika et al. 2008; Prior et al. 1998; Waterhouse et al. 1996) have made some progress in establishing subgroups of individuals with an autism disorder based on the presenting behaviors which interfere with their functioning. However, further investigations are necessary to aid differentiation not only in relation to behavioral topography and intensity but also variations in this behavior resulting from exposure to particular environmental stimuli. Reclassification of individuals with an ASD into clearly defined subgroups, according to suggestions such as those raised here, can only promote a better understanding of their particular needs and clinical treatment to aid effective functioning across the lifespan.

Cluster Reports and Autism

Gayle C. Windham

Division of Environmental and Occupational
Disease Control, CA Department of Public
Health, Richmond, CA, USA

Definition

Using an epidemiological definition, a “cluster” is an aggregation of health-related events or diseases that are grouped together in time and/or space in

greater than expected (real or perceived) frequencies (Centers for Disease Control [CDC] 1990). “Clustering” is usually used to describe aggregations of relatively uncommon diseases, such as cancer or birth defects, in a population or geographic area for which no known cause exists, but may be suspected. This definition will be used, in contrast to, for example, clustering of disease traits or symptoms, such as in ASD, that might be used to classify subtypes of a condition.

Historical Background

Unusual events such as clusters occur regularly, often by chance alone, so there are many considerations that come into defining or further investigating a cluster of disease. From a statistical perspective, it is almost inevitable that some schools, workplaces, or neighborhoods will be associated with clusters of chronic diseases, which may lead to concern on the part of the seemingly affected group. When first noticed, cases with the disease that appear in a cluster are often suspected of resulting from the same specific cause, rather than as independent events (e.g., coin tosses) that happened to have occurred by chance in one place or time period. A cluster may be investigated to help determine whether there is a common cause, in which case the definition of the underlying population in space and time is critical (see below), but even so there are often no reasons identified for the cluster. For example, for a relatively uncommon disease like autism, with a prevalence of about 1 per 68–100 children, in a small enough population, such as a neighborhood, two families with affected children could constitute a greater than expected occurrence statistically, but yield little information on causes.

Infectious diseases typically have time and place components. Investigating clusters (or “outbreaks” in infectious disease), such as the classic church picnic food poisoning, can lead to identification of the source of the disease and thus the means to stop it or prevent it in the future. If clusters are of sufficient size and

importance, they may eventually turn into epidemics. Often, when clusters are recognized, they are reported to health departments or officials in the local area. Breakthroughs and successes in infectious disease control have resulted from the epidemiologic evaluation of clusters of cases; well-known examples include cholera linked to the Broad Street pump in London by John Snow in the 1850s, the investigation of cases of pneumonia at one hotel in Philadelphia in 1976 that led to the identification of Legionnaires’ disease and the ventilation system as a source, and the 1981 report that seven cases of *Pneumocystis carinii* pneumonia had occurred among young homosexual men in Los Angeles, which began the identification of the AIDS epidemic.

Although less common, investigations of non-infectious disease clusters have also resulted in notable examples of breakthroughs linking a health effect to an exposure, such as angiosarcoma among vinyl chloride workers, adenocarcinoma of the vagina associated with maternal use of diethylstilbestrol (DES), and phocomelia with the use of thalidomide. These tended to have a time (vs. space) component with an alert clinician seeing more cases in a short period than expected, but ended up affecting a widespread population geographically. More often, health investigations may not identify the cause of the cluster due to methodologic limitations, usually of small sample size (Wartenberg and Greenberg 1990) or because of the role of chance.

There are several steps to be taken in a careful cluster evaluation, including establishing a specific case definition, so for example, different types of birth defects or cancers are not grouped together; defining the population denominator in person-time; confirming suspected cases and comparing rates to those in the literature; and accounting for known causes (Agency for Toxic Substances and Disease Registry [ATSDR] 2000; CDC 1990). The step of defining the appropriate population, for example, of an entire school versus a few blocks of a neighborhood, or identifying the appropriate exposure period, may result in realizing that the prevalence of the disease is actually within expected. If a cluster is confirmed,

the next step is to assess common factors or possible exposure pathways to generate hypotheses about etiologic mechanisms.

There are numerous methods developed for identifying clusters, sometimes called cluster or geospatial analysis, to determine whether cases are linked in time or place (Rothenberg and Thacker 1992). These can also be used with routine disease-monitoring data to identify spatially related subgroups that may have a common cause or to learn more about etiologic mechanisms. Detailed description of these methods is beyond the scope of this discussion.

Current Knowledge

Clusters of Autism

Few clusters of autism have been published, but this is not necessarily unexpected as reports of clusters may be handled only at the local level. The best known is the Brick Township cluster in New Jersey, initially reported by a parent group concerned about the number of children with autism and environmental issues due to the proximity of several Superfund sites. Their community survey identified an apparently high rate of autism, so the Centers for Disease Control and Prevention (CDC) and the Agency for Toxic Substances and Disease Registry (ATSDR) conducted an extensive investigation in 1998 to identify and clinically confirm all cases (Bertrand et al. 2001; CDC 2000). The prevalence they determined was about four times higher than the frequently cited prevalence in the literature at the time, of 1 per 1000. The exposure assessment by ATSDR did not reveal any links between environmental contamination and the autism cases. When studies with similar methods of intensive case finding were compared, the prevalence was determined to be more similar. Routine surveillance figures for autism were not available in the USA at that time, so this cluster in part led to the implementation of such a system coordinated by the CDC, i.e., the Autism and Developmental Disabilities Monitoring (ADDM) program, which is ongoing (Christensen et al. 2016).

Another parent-initiated report of an autism cluster occurred in the UK, which was also resolved as being consistent with a higher prevalence of autism than commonly known at the time (Baron-Cohen et al. 1999). Further confirming the difficulties of studying small clusters ($n = 7$) and appropriate comparison groups, the rate would only be considered higher than expected when compared to rates in children under age 5 rather than in all those under age 18. A cluster of autism was reported to the Minnesota Department of Health by parents of Somali children; supported by findings about Somali immigrants in Sweden, this led to further investigations to identify possible risk factors (Hewitt et al. 2016; Esler et al. 2017). As is often the case when studying clusters more rigorously, prevalence in Somalis was not substantially higher than in Whites (although higher than other race/ethnic groups), but Somali children with ASD were more likely to have co-occurring intellectual disability than other groups.

There have been popular media reports of “clusters” or higher rates of autism occurring in areas where information technology (IT) companies cluster, such as the Silicon Valley in California. Although not limited to one workplace as would be typical for a cluster, Baron-Cohen et al. (1997) reported that fathers and grandfathers of children with autism were overrepresented in the field of engineering. Two subsequent studies raised the possibility that differences in ascertainment due to SES might explain the results (Jarrold and Routh 1998; Windham et al. 2009). The latter study, conducted in California, did not find that fathers were overrepresented in “high-tech” fields such as engineering and computer programming, but rather mothers were. Further, that study conducted in a six-county region of the San Francisco Bay Area did not find overrepresentation of cases with autism born in the county that includes Silicon Valley, compared to controls. A more recent study reported higher prevalence of autism in a high-density IT region of the Netherlands compared to two other areas, based on school reports, so further investigation will be done (Roelfsema et al. 2012). Such

observations may be related to “clustering” of autism or autistic traits in families, given the strong genetic component, but this is a different topic (see ► “Genetics”, ► “Broader Autism Phenotype”).

Several studies have used complex statistical methods to identify clusters of autism based on geographic residence in order to generate hypotheses about environmental exposures or other drivers of autism prevalence at the local level. Two studies in CA were based on data from the statewide Department of Developmental Services (DDS) database, which has been used for surveillance purposes (Windham et al. 2011), with slightly different birth years and methods. Clusters were identified in both studies; after accounting for several factors, one found the clustering at birth was related to high parental education (Van Meter et al. 2010), which may be related to successfully seeking services for affected children, confirmed by the other (Mazumdar et al. 2013), which reported clusters loosely defined by residence at diagnosis to be in high SES areas and related to neighborhood-level diagnostic resources. Similarly, two other studies of geographic patterns of ASD concluded that factors impacting diagnosis, including maternal age, likely drove the spatial variation observed (Hoffman et al. 2012, 2017). Although raising the limitations of studying environmental factors across wide geographic areas, environmental causes of autism have been increasingly investigated and associated with ASD (Kalkbrenner et al. 2014).

Future Directions

The occurrence of clusters is not predictable, so the merit of further investigation must be considered on an ad hoc basis. As there are now several surveillance systems for autism, cluster analyses could be conducted to identify so-called hot spots and thus possible risk factors. However, these analyses seem less useful for primary study of the etiology of autism, given its broad multifactorial nature.

Blüm Study

Definition

CM-AT™ is an investigational drug candidate developed to potentially treat the core symptoms of autism spectrum disorder (ASD). The drug has received “fast-track” designation from the US Food and Drug Administration. CM-AT™ is a proprietary mix of digestive enzymes that is sprinkled on food in powder form. Materials distributed by the makers of CM-AT suggest that the drug may improve core and associated symptoms of ASD by enhancing the digestion of proteins. A phase III clinical trial of CM-AT™ was completed in 2011, though no data from that study have been published. Further trials are underway.

The hypothesized effectiveness of CM-AT™ is based on the clinical experience of pediatric chiropractor Joan Fallon, founder and CEO of the company that developed CM-AT™. Investigating the stool samples of children with ASD, Fallon observed that many of these children exhibited low levels of fecal chymotrypsin, a proteolytic digestive enzyme. These observations were not published in a peer-reviewed journal, and fecal chymotrypsin levels have not otherwise been reported in the ASD literature. The makers of CM-AT™ postulate that many children with ASD have deficient protein digestion, potentially manifesting in self-restricted diets that are low in protein (see ► [Feeding Problems](#)). CM-AT™ was

developed to compensate for deficient levels of chymotrypsin, potentially improving ASD symptoms by normalizing the digestion of proteins. The mechanism of this therapeutic effect is purported to be an increase in the levels of essential amino acids, some of which serve as precursors in the biosynthesis of monoamine neurotransmitters (see Amino Acids). This mechanism has not been empirically tested in published research to date.

Some aspects of this theory are empirically supported. Children with ASD have been found to exhibit both reduced protein intake (Sharp et al. 2013) and lower plasma levels of essential amino acids (Arnold et al. 2003) relative to non-autistic peers. However, no research to date has been published linking either dietary protein intake or essential amino acid levels in ASD to a reduced capacity for protein digestion. Moreover, correlations between plasma levels of essential amino and ASD symptoms have not been reported in the literature, and no published data exist to suggest that amelioration of an essential amino acid deficiency will improve core ASD symptoms. One prior trial assessing protease enzyme supplementation in children with ASD did not report any significant improvements in ASD symptoms compared to a placebo, though children in the treatment condition did report an increased variety of foods eaten (Munasinghe et al. 2010).

An initial phase III clinical trial of CM-AT™ was carried out from 2009 to 2011, enrolling 182 children with ASD and low chymotrypsin levels between 3 and 8 years of age. While results of the trial have yet to be published, Fallon has stated in an interview that the CM-AT™-treated group showed improvements in irritability and social withdrawal (Zeliadt 2016). In addition, materials on the drug maker's website contend that CM-AT™ was found to be safe and generally well tolerated. An open label extension of this initial trial is ongoing.

In 2015, a second phase III clinical trial of CM-AT™ was initiated, this time enrolling children with ASD and all levels of fecal chymotrypsin. Termed the biologic autism medication (Blüm) Study, the trial aims to enroll an estimated

300 children, aged 3–8 years. The designated primary outcome of the trial is a change in the irritability/agitation subscale of the aberrant behavior checklist (ABC) (see ► [Aberrant Behavior Checklist](#)). A change in the ABC Lethargy/Social Withdrawal subscale is listed as a secondary outcome for the trial. The Blüm Study and its associated open-label extension study are currently in progress.

AXCAM; BIG-2; CNTN4

Structure

Contactin 4 is a neuronal membrane protein. In humans, it is encoded by the gene *CNTN4*, located on chromosome 3p26.3-p26.2, containing 24 exons, and spanning 957 kb. Alternative splicing results in multiple transcript variants. The largest splice variant of contactin 4 (1,026 amino acids) shares 44–66% identity with other contactin proteins. It has six immunoglobulin-like domains, four fibronectin type III-like repeats, one C-terminal glycosylphosphatidylinositol (GPI) anchor to the extracellular part of the cell membrane, and one N-terminal signal peptide. These domains are conserved between the human and rat ortholog (BIG-2). A smaller splice variant (CNTN4A, 282 amino acids) has two fibronectin type III-like repeats and one GPI-anchoring domain (Zeng et al. 2002).

Function

Contactin 4 is a member of the immunoglobulin superfamily of neuronal cell adhesion molecules involved in axon growth, guidance, and fasciculation in the central nervous system. It is a member of the contactin subgroup of these molecules and is believed to function in the formation of axon connections and plasticity in the developing nervous system. Yoshihara et al. (1995) studied the rat ortholog protein, BIG-2, in vitro and found that it promoted neurite outgrowth when used as a neuronal substrate. Overall, their results suggest that this protein has a role in the formation and

maintenance of brain neuronal networks. Subsequently, Saito, Mimmack, Kishimoto, Keverne, and Emson (1998) concluded that this protein is involved in synaptogenesis by studying its expression pattern in the development of rat olfactory sensory neurons.

The expression profile of CNTN4 in the adult human brain has been examined by Northern blot analysis, but these studies are limited in scope. CNTN4 expression is most prominent in the cerebellum, occipital lobe, and frontal lobe, followed by thalamus, cerebral cortex, and substantia nigra (Kamei et al. 2000).

Pathophysiology

Several studies of developmental disorders have implicated *CNTN4* and suggest an important role in normal and abnormal central nervous system (CNS) development. Specifically, disruption of this gene may play a role in 3p-deletion syndrome and autism spectrum disorders (ASD), as evidenced by the studies described below.

Fernandez et al. (2004, 2008b) studied the breakpoints of a de novo balanced translocation (t(3,10)(p26;q26)) in a boy with characteristic physical features of 3p-deletion syndrome who met the criteria for ASD with impaired social functioning, verbal and nonverbal developmental delay, and repetitive behaviors. Fine mapping of the breakpoint on chromosome 3 revealed disruption of *CNTN4*, and this gene maps within the previously defined minimal candidate region for 3p-deletion syndrome. These results suggested a causal relationship between *CNTN4* disruption and 3p-deletion syndrome and a possible relationship with ASD.

Roohi et al. (2009) identified paternally inherited copy number variants (CNV) disrupting *CNTN4* in 3 of 92 subjects with ASD (deletions in two affected siblings and a duplication in an unrelated affected child). This report further implicated *CNTN4* as a candidate gene in ASD.

Glessner et al. (2009) reported a study of genome-wide copy number variation in two ASD and control cohorts. Among other ASD candidate genes, they found a significant increase in

inherited CNV deletions ($p = 0.004$) and duplications ($p = 0.013$) overlapping *CNTN4* in cases versus controls.

Most recently, Cottrell et al. (2011) identified unique nonsynonymous variants of *CNTN4* in 4 of 75 ASD-affected individuals versus 1 of 107 unaffected controls. All variants occurred at highly conserved positions in the gene and were predicted to be deleterious. However, this burden differential did not reach statistical significance or segregate with ASD in all affected families, leaving some question about the role of *CNTN4* variants in ASD pathogenesis.

Overall, there is evidence that *CNTN4* plays an important role in the normal development and maintenance of CNS function. It has been proposed that the molecular basis of *CNTN4* neurodevelopmental functions is conferred by interactions with other proteins (Zuko et al. 2011), including protein tyrosine phosphatase receptor gamma (PTPRG) (Bouyain and Watkins 2010) and amyloid precursor protein (APP) (Osterfield et al. 2008).

Coaching Students with Autism

Alyson Crozier¹, Edoardo Rosso² and Richard McGrath¹

¹School of Health Sciences, University of South Australia, Adelaide, SA, Australia

²ECH Inc., Adelaide, South Australia, Australia

Definition

The definition of coaching is the same when we consider it with reference to people with autism spectrum disorder (ASD) or the neurotypical population. In a sporting context, a coach is someone who uses sport as a vehicle for the development of individuals as performers and as people. Coaching is a form of teaching or instruction as it primarily involves communicating, learning, and maintaining positive relationships with those being taught. The aims of coaching are to understand: how individuals learn so that an effective learning environment can be created, to improve sports technique and develop skills, and to recognize areas for improvement, inside and outside the sporting realm.

Coaches' responsibilities include influencing the development of sport participants in five specific domains: technically (i.e., develop sport skills and abilities), physically (e.g., improve physical condition and develop good health habits), socially (e.g., enhance social skills of participants), psychologically (e.g., managing and controlling emotions), and personally (e.g., learn life skills). All people, regardless of race, ethnic minority, gender, sexual orientation, or ability should have equal access to sporting activities (United Nations Office on Sport for Development and Peace 2011). With this in mind, coaching should not simply be seen as relevant to competitive athletes or sport teams but to anyone with an interest in sporting activities, including the health, recreational, and pure fun dimensions of sport.

Historical Background

Participation in sport and physical activity (PA) provides multiple benefits for young people, including those living with ASD, and it is seen as useful to address a variety of the typical issues associated with ASD (Sowa and Meulenbroek 2012). Besides general fitness-related benefits, youth with ASD who participate in PA and sport may experience improved cognitive, psychological, behavioral, motor, and social functioning, which may contribute to reducing the typical social, emotional, communication, cognitive, and motor challenges faced by people with ASD (Sowa and Meulenbroek 2012). Furthermore, it is maintained that participation in sport and PA can also help young people with ASD – who tend to be considerably more sedentary than their neurotypical counterpart – to develop critical physical literacies, which may in turn equip them for lifelong participation (Smith and Patterson 2012). In this light, participating in sport and PA is “essential” for youth with ASD, “as it provides a sense of normalcy, allows the children to experience a fun activity with their peers, and develops important interpersonal skills” (Ohrberg 2013, p. 53).

However, it can be difficult for youth with ASD to participate in sports and PA, often due to the same issues that sport participation could seek to overcome. This can include low motivation, poor motor functioning, difficulties in self-monitoring, and socializing (Menear and Smith 2011). Sports typically require good eye-hand coordination, a sense of where one's body is in space, and the ability to track a high-speed object. Depending on where an individual lies on the autism spectrum, many young people with ASD may lack the motor coordination required to participate in sport programs aimed at the general population. Further, the social nature of many sports, including the prevalence of both verbal and nonverbal communication, has been identified as a barrier for participation among individuals with ASD. Another issue refers to the fact that, often, people with autism display markedly uneven ability profiles (especially when compared to the neurotypical population, who tend

to have fairly uniform abilities across all areas), typified by both impaired and spared emotional, motor, social, creative, cognitive, and sensory abilities (Boucher 2009). The typical challenges faced by people with ASD and the likelihood of significant differences between the abilities of individuals within any group of people with ASD make the role of the coaches extremely important in promoting greater involvement in sport and PA among this population.

Coaches assume the role of supporting and guiding individuals and teams when socializing them into sports, encouraging enthusiasm for a range of activities, and imparting knowledge and skills on fitness and healthy lifestyle choices. As such coaches, physical educators, and sport managers play a key role in planning, delivering, and monitoring quality programs for youth with ASD. While specialized training would help coaches to gain an appropriate understanding of ASD, coaches are often volunteers lacking access to specialized support and/or knowledge of effective practices to coach individuals with ASD, resulting in adverse consequences for their continued involvement in sport. In order to provide favorable environments that encourage and motivate individuals with ASD to engage in physical activity, programs need to emphasize adaptations to coaching techniques (from mainstream sport) which take into account the range of issues experienced by youth with ASD.

Current Knowledge

Enabling youth with ASD to maintain a physically active lifestyle is important, as it provides opportunities to learn fundamental movement skills, to enhance social interaction, and to develop lifelong habits that incorporate fitness into their daily routines. While studies using movement to “treat” youth with ASD have been conducted as far back as the 1970s (Best and Jones 1974), the use of sport as a tool to assist individuals with ASD to be both physically active as well as attain other potential benefits has received some focus in more recent time. For individuals on the autism spectrum, sport

participation has been found to help youth with ASD to develop fundamental physical literacies, which may equip them for lifelong participation (Smith and Patterson 2012). Adapted programs suited to the needs of youth with autism can elicit positive effects on social behavior (Pan 2010), academic engagement (Nicholson et al. 2011), as well as sensory skills (Bass et al. 2009).

In all sports programs, the role of the coach is extremely important as coaches need to create supportive environments to help participants to improve their skills, learn to relate to specific sports, enjoy peer companionship, and feel socially accepted in a sport setting. As such, it is imperative that coaches understand the individual needs, strengths, and weaknesses of youth with ASD (Ohrberg 2013). However, research has suggested that most physical education teachers and coaches have had limited to no formal training (i.e., workshops) in teaching young people with disabilities (Meegan and MacPhail 2006).

In addition, methods of how to coach children with ASD is often overlooked in the literature (Ohrberg 2013; Rosso 2016), resulting in limited resources for these coaches to draw upon when adapting their sport program. Despite the scarce literature base, several frameworks have been advanced as to how to adapt physical activity programs for individuals with autism. In one instance, it has been suggested that coaching strategies be informed by the Universal Design for Learning (UDL), a framework where curriculum and coaching methods are as flexible as possible to meet the needs of all learners (Sherlock-Shangraw 2013). UDL guidelines suggest that multiple means should be used for (a) representation, (b) action and expression, and (c) engagement. In regard to having multiple means of representation, adapted sport programs should use visual markers, have various means of content delivery, use cue words, have station activities, provide handouts, and attach new information to previous knowledge. Examples of having multiple means for action and expression include the use of white boards to deliver instructions and involve “start and stop” scrimmages to explain the rules of the sport. Last, strategies to provide multiple means of engagement include

developing strategies to set personal and group goals, building communities of practice, incorporating learners' interests into instruction delivery, and allowing for risk-taking while also maintaining a clear/consistent structure.

Another method which has been used to involve individuals with ASD into physical activity programs is the WPPR principle: Watch, Practice, Perform, Reward (MacPhail et al. 2014). In a sport setting, this would result in first watching the coach perform the activity being learned. This is followed by the individual practicing the task repeatedly with support and guidance from the coach. After some practice, the individual then performs the task to his/her highest ability alongside the coach, and if applicable, other children who also are performing the task. Last, individuals are rewarded for every successful goal reached, in order to develop intrinsic motivation.

Further, looking to the physical education literature, it has been suggested that physical education teachers should adapt their classes for individuals with disabilities and developmental disorders (including autism) in three different avenues: assessment, activity selection, and instructional and management techniques (Houston-Wilson 2016). These same principles can apply to coaching, as coaches should begin by carefully selecting the sporting activity that students will engage in. To select an appropriate sport activity, the most important consideration for the leader is to understand and meet the needs and interests of the learners. Further, the activities should allow a high probability of success for participants, and developmental appropriateness and age appropriateness should be considered when selecting activities. In relation to different instructional and management techniques, Houston-Wilson (2016) highlight that strategies that have been helpful in instructing students in the classroom are transferable to sport contexts. For example, using pictures and communication boards, having a consistent structure and routine, and using natural cues in the environment to facilitate the learning and execution of skills would be important for coaches to utilize.

Though these frameworks exist and provide a foundation for developing adapted sport programs, there is limited empirical research evidence which have actually highlighted the specific barriers that individuals with ASD face in a sport-specific setting, as well as how coaches can tailor their coaching strategies to overcome these barriers and meet the needs of participants (Rosso 2016). Given the gap in the literature surrounding how to coach individuals with ASD, recent research has begun to explore how coaches can successfully adapt their coaching techniques to meet the needs of students with autism (Duquette et al. 2016; Rosso 2016).

Several barriers to coaching individuals with ASD have recently been identified (Duquette et al. 2016; Rosso 2016). One particular barrier that can be frustrating when coaching individuals with ASD are the verbal communication issues that can occur between coach and student. Many children with autism do not speak at all, and others have echolalic speech such that they "echo" (repeat) what has been said without fully comprehending its meaning. Further, individuals with ASD often have difficulty understanding the rules, paying attention to instructions, anticipating, and elaborating good strategies. For instance, explaining activities and giving directions involving multiple instructions can be difficult for individuals with ASD to comprehend.

In order to overcome these communication challenges to engage individuals with ASD in sport, multiple strategies have been suggested by both coaches and parents (Duquette et al. 2016; Kraft 2016; Rosso 2016). These strategies include: (1) grabbing participants' attention by saying their name, (2) adapting the instructions (e.g., give less information, give one instruction at a time), (3) utilize cue words that become familiar to participants over time, (4) make sure the participant understands instructions before they participate, (5) use gestures and/or physically perform the behavior to demonstrate, and (6) reward explanations through repetition and the use of visual cues (e.g., pictograms, gestures). Further, the use of positive reinforcement techniques when celebrating the successes of participants was thought to enhance the participants'

enjoyment and engagement in the sporting activity. These can include both verbal communication (e.g., praise) and explicit physical displays of approval (e.g., high fives, fist bumps, victory dances).

Another challenge that exists relates to individuals' gross motor functioning, as some young people with ASD show a lack of coordination, balance, and strength compared with those without autism (Duquette et al. 2016). However, as ASD manifests itself differently in each person, coaches may be involved with teaching multiple abilities at the same time. As such, the coaching strategies used for one participant may not work for another. To combat these challenges, it has been suggested that coaches provide micro-adaptations within each activity and be flexible in adapting to the needs of the individual (e.g., altering the size of equipment or the distance of a kick/pass according to each participant's abilities, Rosso 2016).

Another challenge faced by coaches is determining an ideal coach-participant ratio, particularly in group sport environments. While some participants require one-on-one support in order to understand the basic concepts behind certain sporting tasks, this may not be feasible from a resources perspective in a group setting when trying to engage multiple participants at the same time. A coach-participant ratio of 1–2 or 1–3 has been suggested as an appropriate target in team/group settings, in order to ensure there is individualized support throughout the sport programming when required, while also providing a reasonable degree of interaction with peers (Rosso 2016). However, for young people with ASD, the social environment can also act as a barrier to participation in sport (Duquette et al. 2016). The attitude and reactions of coaches, parents, and peers can all affect an individual with ASD. Thus, retaining a consistent and predictable structure/routine each session and designing activities organized in stations can help to overcome this barrier.

In summary, recent studies have highlighted coaches should use simple instructions, adopt a step-by-step approach, have suitable adaptations,

develop clear session plans, be consistent and predictable in their coaching yet flexible enough to allow late modifications if required, and often remind and check with athletes what has been learnt and what has been forgotten (Duquette et al. 2016; Kraft 2016; Rosso 2016).

Future Directions

While some research and advice has been developed regarding sport coaching for youth with ASD, there remain a number of areas that require further attention. This includes the development of specialized ASD training (sport education program) for coaches involved in adapted sport programs. Adopting a more focused approach to coach training can assist both those involved in coaching as well as provide quality sporting experiences for youth with ASD. Further to this, sporting organizations should develop sport coaching opportunities and pathways for youth with ASD. Rather than focus on youth as participants of coaching, sporting organizations should be exploring the potential of youth with ASD to be coaches. This would not only provide a further expansion of the potential career pathways for youth with ASD in sport but would also provide the opportunity for younger youth with ASD to be mentored within sport by their older peers.

In relation to research, there is a need to create and promote a clearinghouse of “best practice” coaching techniques, tools, and frameworks. While there are some examples of how sport coaching can be adapted effectively for youth with ASD, this is scattered across a variety of publication types (i.e., peer reviewed journals and grey literature). The development of a clearinghouse of case studies would have the potential of further informing and improving sport coaching for youth with ASD.

Another key aspect required regarding research into sport coaching for youth with ASD is the need for longitudinal research. As Sorensen and Zarrett (2014) highlight, there is a need to identify effective interventions concerning youth with ASD in regard to sport and physical activity. However,

much of the research focusing on sport coaching for youth with ASD has been cross-sectional studies within limited time spans. Thus, there is a need to explore the impact of sport coaching on youth with ASD concerning social, behavioral, and educational changes over time.

Synonyms

[Inner ear](#)

Definition

The cochlea is the auditory portion of the inner ear which is embedded in the temporal bone. It consists of membranes, fluids, hair cells, and VIII

nerve endings. The organ of Corti, housed in the snail-shaped cochlea, contains many cells, including the inner and outer hair cells, and is responsible for converting mechanical energy from the middle ear into electrical energy. That energy is passed to auditory nerve fibers.

²Long Island University, Brooklyn, NY, USA

³Endicott College, Beverly, MA, USA

Skinner (1957) proposed a system of classifying verbal behavior, by function and form, resulting in discrete units of analysis termed *verbal operants*. The taxonomy is based on the forms of the antecedent controlling stimuli and response products and the specific consequences provided for each operant. Skinner's original categorization included the following operants: *echoic*, *mand*, *tact*, and *intraverbal*. However, these categories of behavior do not encompass all forms and functions of communication and language. Two additional categories have since been proposed: *codic* and *duplic* (Michael 1982).

The form of a verbal operant is said to have *point-to-point correspondence* when the individual components (e.g., letters, syllables) of the antecedent stimulus and response product forms match. And, when the sense mode of the stimulus and response is the same (e.g., auditory stimulus and vocal response), they exhibit *formal similarity*. The function of each verbal operant is determined by controlling consequences or motivating operations (*mand* only). Controlling consequences are changes in stimulus conditions that follow the occurrence of verbal operants (e.g., praise), whereas motivating operations are environmental variables that alter the effectiveness of some stimulus as a reinforcer and alter the frequency of behavior that has been reinforced by that stimulus (e.g., hunger).

A *codic* is a verbal operant in which the antecedent stimulus and response product forms exhibit point-to-point correspondence, there is no formal similarity, and that is reinforced by generalized conditioned reinforcement from a listener (usually a parent/guardian or teacher). Common examples of *codics* include reading written words (textual (In the case of the *textual*, reading means "decoding" words and not comprehension)) or writing words that one hears spoken aloud (taking dictation). *Codics* are learned through both direct and incidental teaching strategies and are reinforced by the learner's verbal community with praise or some form of educational reinforcement.

Definition

Cognitive behavioral therapy (CBT) treatments are based upon cognitive science models of the mind and mental life. Contemporary CBT treatments have been particularly influenced by the memory retrieval competition model (e.g., Brewin 2006). Conceptualized in information processing terms, CBT aims to promote *retrievable memories* of adaptive responses that can successfully compete with and suppress memories of previously learned maladaptive responses evoked under “real-world” conditions outside the therapy office. This process leads to an increase of

realistic appraisals of the environment and the self, more appropriate behavior, and greater capacity to regulate strong emotion.

Historical Background

Cognitive behavioral therapy is rooted in traditions of behavioral and cognitive (or rational) therapy. During the early behavioral learning theory experiments of the early twentieth century, many of which were conducted with animal subjects (e.g., by Pavlov, Thorndike, and Hull), several case studies were conducted with fear conditioning in children. Watson and Rayner (1920) and Mary Cover Jones (1924) used applications of classical conditioning to induce or eradicate fears (phobias) in young children. These are generally considered the earliest behavior therapy cases (Rachman 1997). Skinner, with the advent of radical behaviorism, popularized applications of operant conditioning for modifying human behavior; this was quickly applied to a variety of developmental and psychiatric conditions including autism (e.g., Ferster and Demyer 1962; Lovaas et al. 1971), with some early successes in basic abilities such as imitation and language use. Concurrent with these developments in behavior therapy, prominent researchers were publishing data suggesting that traditional psychodynamic psychotherapies were proving ineffective with individuals with autism (e.g., Kanner and Eisenberg 1955; Rutter 1968). Behavior therapy remains a staple component of modern CBT, including CBT treatments for people with autism.

Cognitive and rational therapies (referred to as cognitive therapy for the remainder of this entry, for simplicity) emerged in the context of the “cognitive revolution” in psychology, which rejected the thesis of radical behaviorism that mental states, such as thoughts, were unmeasurable and inconsequential. Cognitive psychology, with models of attention, memory, perception, and language, and their integration, underlies the original cognitive therapies developed by Ellis (1957) and Beck (1963). A core principle of cognitive therapy is that certain “errors” of thought

(misperceptions, misattributions, all-or-nothing thinking, etc.) lead to inappropriate emotional reactions, behaviors, or both. The underlying model is often referred to as a cognitive appraisal theory of emotion (cf. Lazarus 1991); the idea being that thought in its various forms drives emotion and behavior. A key therapeutic technique in the early cognitive therapies was the use of logic to identify and challenge faulty thought processes. The assumption was that irrational thoughts would be “replaced” with more rational ones, leading to improved emotional states and behavioral responses. Indeed, early research on cognitive therapies offered evidence of good treatment response in terms of symptom reduction, particularly with regard to emotion disorders such as anxiety and depression (Beck 1970; Watkins 1975). Relatively little cognitive therapy research was conducted with individuals on the autism spectrum in this early period.

As the cognitive and behavioral traditions merged into integrative CBT packages, core methods used to achieve symptom remission emerged: psychoeducation (learning about the nature of one’s mental health condition), Socratic questioning and collaborative discussions to build up awareness of thought and emotion and to teach thought- and behavior-based coping skills, and behavioral experimentation, in which alternative responses to challenging situations are attempted in real-world settings and then reflected upon in structured discussions in order to build up potent memories of adaptive patterns of thought and behavior for future use in similar (not necessarily identical) situations (e.g., Brewin 2006). At present, there is increasing interest in the application of CBT to individuals with ASD, as described below.

Rationale or Underlying Theory

With the increasing fund of knowledge emanating from cognitive science research in recent decades, a number of critical findings were published that helped refine the model of mental states in cognitive psychology (see, e.g., Anderson et al. (2004) model of the architecture of the mind).

A generally accepted view from the modern literature is that long-term memories can be nearly indelible and that it is common to have multiple, competing memory representations (schemata) of the same event or concept (Brewin 2006). Hence, rather than “replacing” maladaptive thoughts with adaptive ones, it is more likely that new adaptive thoughts can be learned and strengthened using certain memory enhancement techniques, and, under certain conditions, these new memories can partially or fully suppress older maladaptive memories. Promoting such learning is, in fact, a fundamental goal of contemporary cognitive therapy (e.g., Brewin 2006). Nonetheless, the older maladaptive memories are likely still accessible and can return to consciousness under certain conditions (e.g., Rodriguez et al. 1999) underscoring the “indelibility” of many memories and the challenge facing therapists endeavoring to help individuals cope more effectively and employ more useful skills under varied conditions. These properties of human memory have led cognitive therapists to a memory retrieval competition model of therapy that endeavors to enhance recall of beliefs and skills under challenging conditions that promote adaptive responses (Brewin 2006).

Although cognitive and behavioral therapies were developed in parallel in the middle of the twentieth century, cognitive therapy had behavioral elements right from the beginning. For example, clients were encouraged to challenge their negative views about specific situations by engaging in “behavioral experimentation” and testing these situations out in person (e.g., initiating a brief conversation with others in a social group in which one feels like an outsider to test whether one will be rejected). Although such strategies involve behavioral change, the goal is not specifically to develop a new response linked with a given condition (e.g., a behavioral view of clinical change) but rather to acquire new information that can promote adaptive beliefs about the situation that, with sufficient rehearsal, can occlude the current unrealistic, negative perceptions of the situation and therefore change behavior.

Although behaviorism and the cognitive science perspective emphasize different aspects of

human learning and memory in the service of behavioral change, the two approaches are not necessarily at odds. The extreme view of radical behaviorism, rejecting the importance of mental states, is not commonly practiced in modern psychology, even among those who subscribe to behaviorism as a primary explanatory and clinical tool. Fundamentally, learning via association and learning via higher cognitive processes (e.g., conceptual reasoning) are complementary and may occur either in serial or in parallel in any given learning situation. Cognitive behavioral therapy, accepting this affinity between the behavioral and cognitive perspectives, sought to capitalize on all effective means of human learning – tailored to the cognitive and developmental level of a given population – to promote clinical change. As a result, often multiple treatment techniques spanning both associationist and cognitivist approaches to clinical change are combined into CBT treatment “packages” that layer multiple forms of learning together. Examples are CBT programs for anxiety disorders that involve a number of thought-based approaches to change (e.g., cognitive restructuring; mindful awareness) married together with associationist approaches such as gradual exposure to feared stimuli and self-reward (e.g., Kendall 1994) and CBT programs for depression, which combine identifying and challenging “erroneous” ways of thinking (e.g., all-or-nothing thinking) with behavioral techniques like self-modeling and pleasant activity scheduling (e.g., Weisz et al. 1999). These two basic modalities of learning are thought to complement one another and promote more comprehensive formation of adaptive memories.

Goals and Objectives

CBT is intended to treat a wide variety of mental health and developmental disorders, although the target population is expected to have some capacity to communicate and, thus, benefit from mainline cognitive techniques (in contrast, many purely behavioral therapies do not assume substantial functional communication, particularly those used in the treatment of ASD). Historically,

the most common targets of treatment for CBT have been mood and anxiety disorders (including obsessive-compulsive disorder; OCD), with high levels of evidence for treatment efficacy in both conditions (Butler et al. 2006; James et al. 2005). There are CBT-based programs for many other conditions as well, with somewhat more tentative levels of support due to either a lack of large, rigorous studies or mixed results. Disruptive behavior disorders, habit disorders, substance use disorders, psychotic disorders, and personality disorders are among the other conditions commonly treated with CBT. Autism spectrum disorders have also been the target of some recent CBT programs. Most of these latter programs have focused on associated symptoms (e.g., anxiety) in individuals with ASD (e.g., Sofronoff et al. 2005); several have targeted core autism symptoms (e.g., social engagement) as well (e.g., Wood et al. 2009a).

As noted in the section on rationale, contemporary CBT aims to build up the strength of memory for adaptive responses – thoughts, emotions, and behaviors – when individuals are in challenging situations that typically elicit maladaptive responses. Here are some examples of maladaptive responses of various types, particularly those that are commonly seen in ASD (see, e.g., case studies presented in Sze and Wood 2007, 2008; Lehmkuhl et al. 2008):

- The belief that others are scrutinizing one’s every move (leading to anxiety, dysfluency, tentativeness, and reticence)
- A belief that life is not worthwhile because it is full of challenges (leading to sadness or irritability, retreat into comforting but solitary activities like electronics, or self-harm)
- The belief that nothing short of perfect is good enough, so why try if that is not attainable (leading to avoidance of specific tasks viewed in this light and, often, conflict and anger stemming from social pressure to make an effort anyway)
- The belief that rules are inviolable and absolute (leading to behaviors such as tattletaling as well as the sadness that often ensues after experiencing rejection from others regarding

this behavior or telling on oneself as often seen in pediatric OCD and the anxiety that accompanies that behavior)

- An individual's belief that others are uninterested in talking or playing with him/her because they have not always responded positively to the individual's ideas in the past (leading to anxiety and social avoidance)
- A corresponding belief that playing with others is mostly about getting to choose the game and set the rules, winning, and having the longest possible turn, rather than enjoying an activity together and the sociability that goes with it (leading to egocentric, self-oriented behavior, poor sportsmanship, and, often, ultimately sadness at the negative social feedback that can ensue)

With regard to these types of maladaptive responses, CBT aims to help individuals challenge faulty assumptions by using logic, evidence, and direct observation to arrive at more realistic conclusions and alter behavior accordingly. With the adoption of realistic beliefs and corresponding behaviors often comes emotional relief. For example, in response to anxious beliefs about being scrutinized by others, many CBT programs would encourage an individual to challenge these beliefs by using logic and simple behavioral experiments (e.g., tripping on purpose in public or other "mistakes" to test what types of reactions one receives) to foster new attitudes (e.g., "people really do not care about a lot of minor mistakes you might make, and as for big ones, it is their problem if they laugh at you, not yours") and corresponding behaviors (e.g., taking more risks in public) (e.g., Kendall 1994). Improvement in emotional states is expected to follow successful acquisition of these kinds of adaptive beliefs and behaviors. Some forms of CBT also involve adopting a disengaged attitude with regard to one's negative emotions – an approach that aims to change cognitive appraisal of emotion to reduce the intensity and aversiveness of states such as sadness, anxiety, and perseverative thought (Ost 2008).

A fundamental difference between CBT and strictly behavioral treatments (e.g., operant or classical conditioning-based models) is the

conceptualization of mechanisms of change and complementary intervention techniques. While purely behavioral interventions assume that largely automatic (and unobservable) learning processes (e.g., extinction, associative learning, modeling) promote behavioral change and symptom remission, CBT-based models seek to promote changes in thinking and volitional behavior (e.g., identifying and challenging maladaptive interpretations of social situations) that are adaptable to multiple situational contexts. A simple example of phobia treatment illustrates differences between CBT and purely behavioral approaches: in the former, catastrophic beliefs about a feared stimulus would be identified and challenged to build up to facing the phobic stimulus, and after habituation occurs, the therapy would promote the development of principles for thinking about the feared stimulus differently to build a benign memory schema of the stimulus that could compete with and suppress the fearful schema that the patient had prior to treatment (e.g., Wood and McLeod 2008). In contrast, a purely behavioral approach would involve gradual exposure to a feared stimulus to achieve extinction of the conditioned (fearful) response with no emphasis on related thoughts, and when fear and avoidance were eliminated in one setting, the procedure might be repeated in several other settings in an effort to achieve generalization. Clearly, the putative learning processes and corresponding techniques used to promote change differ significantly in these two types of treatments (further description of CBT technique is given below).

Treatment Participants

CBT has been found efficacious across a wide range of populations, particularly in neurotypical groups. Typical pediatric and adult populations affected by depression, anxiety, and other psychiatric conditions have shown good treatment response with few limitations (Norton and Price 2007; Weisz et al. 2006; In-Albon and Schneider 2007). Although numerous studies of predictors of treatment response have been conducted, few

consistent trends have emerged. The method of delivery is undoubtedly influential, however. The younger the children are, the more likely they are going to need parent involvement. Children with ASD also appear to do better with parent involvement than with child-only CBT (Sofronoff et al. 2005; Puleo and Kendall 2011). No reliable differences have been found with regard to gender or comorbidity. It is assumed that greater intellectual ability should promote greater understanding of the cognitive therapy aspects of treatment, all other things being equal, but this has not been studied carefully. Furthermore, appropriate modifications of treatment for individuals with intellectual disabilities may make CBT accessible and comparable in effectiveness across a wide range of intellectual functioning (Suveg et al. 2006).

Treatment Procedures

CBT is generally presented in an interactive tutorial format, with a lesson plan, some form of instruction, practice, and review. Although it is relatively structured, CBT is responsive to client characteristics, interests, and level of engagement. Forming a positive alliance with the client is an ongoing goal in CBT to enhance the client's motivation to learn and use skills (e.g., Chiu et al. 2009). CBT for mood- and anxiety-related problems typically involves teaching cognitive and behavioral skills followed by a skills practice phase in simulated and "real-world" situations (e.g., Kendall 1994). In one of the more influential clinical trials of CBT for pediatric anxiety disorders in typically developing youth, Kendall et al. (1997) found that the *cognitive* intervention aspects of the treatment (e.g., challenging irrational beliefs) alone were not effective in reducing children's anxiety levels. Only when cognitive training was paired with in vivo exposure elements (facing fears rather than avoiding them) did CBT become an efficacious intervention.

For individuals with ASD and concurrent anxiety, the general CBT approach of challenging irrational fearful beliefs and developing rational beliefs is employed, although other elements of treatment have varied widely from program to

program. In these programs for individuals with ASD, there has been wide variation with regard to the emphasis placed on in vivo exposure relative to other treatment elements (e.g., cartooning, role-playing). At the extremes of the continuum, the Wood et al. (2009b) program involves in vivo exposure at home on a daily basis for the majority of the 16-session treatment, which spans 4–5 months for most youth; whereas the Sofronoff et al. (2005) 6-session treatment focuses on a series of creative anxiety management skills tailored for youth with ASD, but with no explicit in vivo exposure elements. Some (but not all) CBT trials conducted with typically developing children and youth with anxiety disorders (e.g., Barrett et al. 1996; Barrett 1998; Wood et al. 2006) have found that including parent training in the intervention leads to superior intervention effects as compared to exclusively child-focused treatments. Many of the group design studies for youth with ASD and high anxiety have included concurrent child- and parent-intervention components.

The majority of the treatment programs that have been studied for individuals with ASD have used a group-therapy treatment format with a structured sequence of sessions for all participants. Others have used an individual therapy format with modular design (see Chorpita et al. 2004) in which individual treatment components were selected by the therapist and supervisor on a session-by-session basis using a clinical algorithm matching the client's presenting characteristics with corresponding treatment elements (e.g., Wood et al. 2009a, 2009b). As an example, a child who was socially anxious at school would receive a social coaching module in which social approach behaviors are broken down into steps, anxious beliefs about each step are discussed and challenged, and then steps are practiced in various real-world settings such as parks and school playgrounds repeatedly until a sufficiently advanced level of the skill (e.g., joining recess games without fear) is evidenced consistently. No clinical trials thus far have compared the relative efficacy of structured group-format CBT interventions with individually administered, modularized interventions of this kind.

Anger and aggression have been the target of some CBT programs, particularly in neurotypical youth (e.g., Kazdin 2005). In a randomized controlled trial conducted by Sofronoff et al. (2007), a CBT program was devised to address anger problems in youth with ASD. Treatment consisted of six weekly 2-h sessions for both child and parent. The manualized therapy sessions focused on exploring positive and negative emotions, cognitions related to coping with anger, social stories to promote emotion management, and designing individualized coping plans for anger management.

With regard to treatments for ASD symptoms – such as social deficits – only a few programs have been developed within a CBT framework. Bauminger (2002) developed a school-based CBT program, noting that maladaptive cognition accounts for some of the interpersonal behavior in youth with ASD and that, therefore, adaptive alterations to cognitive structures could make a positive impact on interpersonal behavior. In the Bauminger (2002) intervention, several elements are notable: children's classroom teachers are responsible for a 3-h-per-week, 7-month intervention conducted at school that relies heavily on guiding a dyad consisting of the target child and a typically developing peer through a series of 13 social skill lessons (e.g., cooperating) that are to be practiced at recess, on the phone, on playdates, and so forth. Parents are also asked to support children in learning and implementing these social skills. The intervention was presented by the teacher to the dyad, allowing for individualization (e.g., by having pairs of children choose activities that they both liked). The Wood et al. (2009a, b) program, described above, also addresses social and repetitive symptoms of ASD, integrating these target symptoms into the treatment hierarchy with emotion-related symptoms.

Efficacy Information

CBT treatments for anxiety in ASD have been generally successful. Sofronoff et al. (2005) evaluated two variants of a 6-week CBT program for

anxiety in youth with ASD in group-therapy format. Parent-report measures showed declines in child anxiety symptoms in the CBT groups as compared to a wait list group. Similarly, in 12- and 16-week group-therapy CBT interventions for comorbid anxiety and ASD in children, Chalfant et al. (2007) found that anxiety outcomes were superior for the immediate treatment group relative to the wait list arm. However, limitations of these studies were that the study therapists, rather than independent evaluators blind to treatment assignment, administered the posttreatment diagnostic interviews and that treatment fidelity was not assessed. Reaven et al. (2009) studied 33 children (aged 8–14 years) with ASD and comorbid anxiety disorders and, using a nonrandomized assignment paradigm, assigned them to immediate treatment in group-therapy format CBT or a wait list. Outcome measures were child- and parent-reported anxiety symptoms using psychometrically sound questionnaires. Youth in the immediate treatment group improved more than the waiting list group on parent-reported symptoms, but not child-reported symptoms. This may have been attributable to low pretreatment child-report symptom scores.

White et al. (2009) examined a manualized 11-week CBT program for the treatment of anxiety in four youth aged 12–17 years with high-functioning ASD. The program consisted of individualized therapy sessions with high levels of parent involvement and group-therapy sessions mainly for the teaching and practicing of social skills. At posttreatment, three of the four adolescents no longer met diagnostic criteria for their targeted anxiety disorder and showed significant reductions in anxiety based on parent report. In a study of a manualized, individualized CBT program, 40 children aged 7–11 years were randomized to either 16 sessions of CBT or a wait list (Wood et al. 2009b). Participating children had an average of 4.18 psychiatric disorders at intake. Despite the high level of comorbidity, children randomized to CBT had primary outcomes comparable to those of other studies treating childhood anxiety in typically developing patients (see, e.g., Barrett et al. 1996; Wood et al. 2006), with large effect sizes for most outcome measures;

remission of all anxiety disorders for over half of the children by posttreatment or follow-up; and a high rate of positive treatment response on the Clinical Global Impressions–Improvement scale (CGI-I) (78.5% from intent-to-treat analyses). As with the Reaven et al. (2009) study, child-reported anxiety did not differ significantly from pre-treatment to follow-up; however, a floor effect was expected, as baseline levels were low and decreased with treatment.

In the Wood et al. (2009a) CBT intervention ($N = 19$), there was also a statistically significant difference between the CBT group and the wait list group at posttreatment/post-wait-list on total parent-reported autism symptoms on the Social Responsiveness Scale, with a medium to large effect size. Treatment gains were maintained at 3-month follow-up. Of course, this study was limited by a small sample and reliance on parent reports of symptomatology, which are vulnerable to bias. Evidence-based assessments of core autism symptoms based on independent evaluators' ratings and direct observations of children's behavior (e.g., the ADOS) should be employed in future studies of CBT programs like this one to determine their potential for reducing the expression and severity of core autism symptoms.

In the Sofronoff et al. (2007) anger management CBT program, there was a significant reduction in the number of parent-reported anger episodes after treatment in the immediate intervention group, with gains maintained 6 weeks after treatment completion. Qualitative interviews conducted with participants' teachers post-treatment revealed participants' use of strategies they had learned through the program to manage their anger within their classroom. One methodological weakness in this study was that no diagnostic criteria or operational definition of an externalizing disorder was used for case selection at pretreatment. In addition, all outcome measures were parent-report, with the exception of the qualitative interviews with teachers.

In the Bauminger (2002, 2007a) individual interventions for social deficits in ASD, a pre-post design without control group was used, and children approximately doubled their number of observed positive social interchanges with peers

in naturalistic observations at school – particularly eye contact, expressions of interest in others, and talking about their own experiences. They were more likely to initiate positive interactions than they were to respond positively to peers' initiations to them. Teachers also rated children as improved in certain positive social skills on the Social Skills Rating Scale. A 4-month follow-up assessment provided evidence of maintenance of treatment effects (Bauminger 2007a). This treatment model is promising and merits a more thorough evaluation in a randomized trial.

A group-therapy CBT treatment (with 3–6 children per group, at least half of whom were typically developing) with many commonalities with the Bauminger (2002) intervention, but focusing more on within-group interaction as a vehicle for learning, was also evaluated by Bauminger (2007b). Again, an AB design was used ($N = 26$). While there was substantial improvement in social behaviors among the therapy group members while interacting during the sessions from pre- to posttreatment, this effect did not generalize to the playground setting, in which no significant improvement was found in social behaviors over the course of the 7-month interval from baseline to posttreatment. Since Bauminger essentially adapted the therapeutic concepts and methods from her more individually oriented CBT interventions (Bauminger 2002, Bauminger 2007a) for this group-therapy trial, it is worth considering whether there is more merit in individually oriented social interventions in autism (if, as Bauminger notes, the child's ecological influences are addressed through the individual intervention), as compared to group-based interventions, than has traditionally been assumed.

Outcome Measurement

In defining desirable study features for research intended to establish efficacious treatments, Chambless and Hollon (1998) noted that it was important that valid and reliable measures of symptom counts or diagnostic status, preferably including those rated by an evaluator blind to treatment status and study hypotheses, be used

as primary outcome measures. Of the small number of controlled trials of CBT for individuals with ASD, most have included this kind of measure. Many of these have focused on comorbid mental health features such as anxiety (e.g., Chalfant et al. 2007), and one of these trials utilized a parent-rated measure of core autism symptoms that is norm-referenced and used in the diagnosis of ASD (Wood et al. 2009a). The Bauminger studies also used observational measures in the school setting, an objective measure with high ecological validity. Many of the studies of CBT in ASD have also used parent-, teacher-, or self-report, which are useful as secondary indices of treatment outcome but may be biased by expectancy effects and other sequelae of being unblinded.

Qualifications of Treatment Providers

Practitioners are generally licensed clinical psychologists with a doctoral degree in psychology. However, other professionals with licensure to provide psychotherapy to children (e.g., school psychologists, licensed clinical social workers, child and family therapists) with appropriate training can conduct CBT treatments. Regardless of specific license and degree, a specialization in individuals with ASD and specific training (including one-on-one supervision) in CBT for individuals with ASD are essential qualifications for the professional delivery of this type of treatment.

Definition

Cognitive behavioral therapy (CBT) is an evidence-based psychosocial practice for the treatment and primary prevention of anxiety in typically developing children, adolescents, and adults (Chorpita 2007). Recently, different formats of CBT programs have been adapted and used for the treatment of anxiety in children with autism spectrum disorder (ASD). The main purpose of CBT is to help individuals identify and replace negative and unrealistic thoughts with more meaningful positive thoughts, so as to treat both emotional and behavioral problems (Ellis 1962; Beck 1963). CBT programs include a number of cognitive and behavioral problem-solving and coping strategies to enable individuals to identify the contexts, conditions, or precursors that lead to anxiety and then self-manage the symptoms when they appear. Structured manual and modular CBT intervention programs have been implemented in both individual and group formats for varying lengths of time in mental health settings (Perihan et al. 2019). Structured manualized programs include specific sessions for the targeted group. Examples of structured manualized CBT programs are Coping Cat (Kendall and Hedtke 2006) and Skills for Academic and Social Success (Warner et al. 2007). A limitation of the structured manualized programs relevant to ASD is that the manualized approach may not have the flexibility necessary to customize interventions based on the needs of an individual. Modular programs allow for more flexibility and may be tailored to meet and address a wider range of unique needs of children and adolescents (Chorpita 2007).

Current Knowledge

Greater concerns have been expressed in recent years regarding comorbid mental health problems for children with ASD (Ung et al. 2014). Anxiety is a common problem among children and adolescents with ASD (Vasa et al. 2014). Children with ASD tend to be at higher risk for developing significant levels of anxiety than typically developing children (White et al. 2009). While the prevalence of anxiety disorders in typically developing individuals is estimated to be up to 8% (American Academy of Pediatrics 2019), some studies indicated that 40% to 84% children with ASD either meet the diagnosis criteria for various anxiety disorders or report high rates of anxiety (Sukhodolsky et al. 2013). Moreover, the prevalence of anxiety disorders and symptoms in individuals with ASD is also higher than individuals from other disability groups (Vasa et al. 2014). Due to these facts, several studies have been conducted to obtain more information regarding the nature of anxiety symptoms in children with ASD in order to investigate possible overlap in anxiety symptoms and ASD characteristics. Notably, studies have affirmed the similarities between anxiety symptoms and core symptoms of ASD (Wood and Gadow 2010). Recently, Kerns et al. (2014) indicated that some individuals with ASD showed atypical anxiety symptoms that were not consistent with any DSM-5 criteria. As of now, anxiety symptoms of children with ASD are commonly measured by standardized assessment measures that have been developed for assessing anxiety symptoms in typically developing children (Sterling et al. 2015). Examined together, these factors may cause children with ASD to remain unidentified or insufficiently supported in both social and school environments. Nonetheless, while the actual rate of anxiety in children with ASD remains unclear, already identified individuals with a high level of anxiety should be able to receive the best treatment options available.

Children with ASD typically have difficulties in social interactions, communication, and academic performance (American Psychiatric Association [APA] 2013; Leyfer et al. 2006). High levels of anxiety exacerbate these characteristics

and further negatively impact their abilities across the school, home, and community environments (Reaven et al. 2008; Sukhodoldky et al. 2008). Without intervention, high levels of anxiety experienced by many children with ASD may lead to additional mental health problems such as depression, substance abuse, and suicide attempts (Fujii et al. 2012). In recent years, there is also a growing body of research that has illustrated that most children with ASD face difficulties in using their cognitive potential to communicate or build social relationships, which leads to developing high levels of anxiety (Estes et al. 2011). Given the high prevalence of anxiety in children with ASD, there has been a recent push for the implementation of CBT as an evidence-based treatment program to treat anxiety in children with ASD (Clarke et al. 2016).

CBTs are considered primary treatment options for anxiety in typically developing children across different settings. Seligman and Ollendick (2011) indicated that over 269 meta-analytic studies have demonstrated the efficacy of the CBT for the treatment for wide range of problems including the efficacy of CBTs for children and adolescents with anxiety disorders. Overall, these studies indicated that two-thirds of children with anxiety disorders showed no anxiety symptoms after CBT (Seligman and Ollendick 2011). Although much of the current literature on CBT involves typically developing children, increasing attention is currently being given by researchers for using CBT to treat anxiety symptoms in children with ASD. Findings of randomized controlled trial studies, as well as meta-analyses, support that children with ASD benefit from CBT treatments for anxiety disorders (Ung et al. 2014). Moreover, the current evidence provides support to use CBT for children with ASD. However, implementations of CBT programs with adaptations for ASD require additional research on the necessary adaption components, and future studies need to be conducted that have better implementation fidelity of the CBT programs for children with ASD (Perihan et al. 2019).

A growing number of studies have begun to examine the efficacy of CBTs for anxiety in children with ASD, and an increased body of research

has demonstrated that CBT is an effective treatment with adaptations for these youth (Ung et al. 2014). A recent meta-analysis (Perihan et al. 2019) reported that CBT appears as an effective treatment option for children with ASD. Twenty-three published studies of CBT for anxiety in children with ASD were included. Studies varied in sample size from 6 to 69 participants and used varied types of CBTs lasting between 4 and 32 weekly sessions. Outcomes were assessed by examining different types of parent, child, and teacher questionnaires which were designed to measure anxiety in typically developing children. Results yielded a moderate effect size ($g = -0.66$) for the reduction of anxiety symptoms; children who received CBT treatment had reduced levels of anxiety.

To understand potential factors that affect treatment responses of CBT for anxiety, parental involvement and treatment lengths were examined. Several studies have demonstrated that parents of children with ASD are at increased risk of having a higher level of parental stress than parents of typically developing children (Conner et al. 2013). Researchers have paid particular attention to exploring the relationship between parental anxiety and anxiety symptoms in individuals with ASD, as well as possible effects of parental anxiety in treatment response (Reaven et al. 2015). Analysis of parental involvement indicated that individuals with ASD received the most benefit from CBTs when parents were involved in the interventions. This finding provides additional support for the research that expressed that parents may play a critical role in changes in child anxiety (Sofronoff et al. 2005). Moreover, the involvement of parents in CBT programs provides an opportunity to assist children in practicing coping skills when they are faced with challenges outside of school (Weiss et al. 2014). Surprisingly, a few studies showed that parents also derived benefits from their involvement in CBT treatments. They were able to apply the key CBT concepts to themselves to manage their feelings, as well as to reduce both their anxiety and parental stress (Ooi et al. 2008; Reaven et al. 2015). This finding points to the possible impact of parental involvement on

treatment responses of CBT for anxiety in this population.

Recently, studies have consistently noted that children with ASD may need extended time to understand and apply newly learned cognitive strategies for coping with their feelings (Clarke et al. 2016). Thus, the recent meta-analysis (Perihan et al. 2019) aimed to investigate the possible impact of the treatment length on treatment response. Findings demonstrated that treatment effects associated with short-term interventions were significantly weaker than those obtained in standard-term and long-term interventions. Some studies have also aimed to increase the efficacy of interventions in a short period of time (e.g., 1 week) by extending the contact time with clients. However, the results of the studies suggest that extended time rather than more contact time is required for the clients to learn and apply the cognitive strategies implemented. It is thus likely that children also need extended time rather than more contact time to learn and apply cognitive strategies for coping with their anxieties.

Future Directions

A major focus in the development of CBT for children with ASD is the continuing adaptation for school-based settings. In 2014, about 1 in 59 children were identified with ASD by age 8; that statistic is constantly increasing. Furthermore, anxiety-related symptoms are significantly common problems in children with ASD (White et al. 2009). CBT is one of the most effective evidence-based treatments of anxiety in typically developing children, and a growing body of research, including the previously discussed meta-analysis, have clearly documented the impressive results of CBTs in treating anxiety among children with ASD. However, while CBT, especially CBT with modifications or adaptations for ASD (Perihan et al. 2019), appears helpful, some recommendations should be considered for future studies.

The first and most important consideration for future studies is transferring CBTs from clinic to school settings. The focus on inclusion in schools

means a greater number of students with ASD are going to be placed and be educated in general education classrooms with their typically developing peers (Feraoli and Harris 2011). A substantial body of research has demonstrated that children with ASD already face difficulties in social interactions and communication (APA 2013). The move toward inclusion of students with ASD is likely to exacerbate those social interaction and communication programs and increase the level of anxiety experienced by this population. Despite school being an appropriate environment for intervention programs for children with ASD, most of the previous studies were of CBTs delivered in clinic settings by clinicians (Perihan et al. 2019). In a review of the literature, Perihan et al. (2019) found medium to large effect sizes that ranged between -2.40 and -0.40 for school-based CBT treatments in children with ASD (e.g., Clarke et al. 2016; Fujii et al. 2012). These findings provide initial support for the delivery of CBT programs in school settings by a range of professionals – such as teachers and counselors with appropriate training and supervision (Clarke et al. 2016). Introducing CBT programs into school settings that are administered by school professionals will also increase the accessibility of treatments of anxiety for children with ASD (McConachie et al. 2013). Otherwise, the limited number of clinicians will contribute to fewer students being treated in school systems.

Today, the treatment of anxiety symptoms with CBT in children with ASD is still progressing, and researchers are continuing to identify the modifications and adaptations that should be made to existing CBT programs to meet the needs of children with ASD. For future studies, evidence-based guidelines may be required to examine whether these modified CBTs have been implemented accurately with necessary quality components to ensure they are efficient and generalizable (Seligman and Ollendick (2011). As such, it is necessary to include implementation fidelity in studies to investigate the quality of each CBT program or protocol used.

Last, there is continuing uncertainty about the measures used to evaluate anxiety in children with ASD. Most studies have used outcome measures

that have been designed to assess anxiety symptoms in typically developing children. It is becoming clear that children with ASD may possess atypical anxiety symptoms which may not be captured by existing measures (Kerns et al. 2014). There is also emerging evidence for similarities in anxiety symptoms and ASD characteristics (Bellini 2006). Social interactions and communication problems are primary characteristics of children with ASD, which may increase levels of anxiety. Likewise, the difficulty of school settings may increase or intensify the levels of anxiety in children with ASD (White et al. 2009). In order to make a distinction between anxiety symptoms and autism characteristics, future studies should include outcome measures specifically for assessing the autism vs. anxiety symptoms of children with ASD.

Definition

The important cognitive factors associated with reciprocity in children with autism spectrum disorder (ASD) include the social-cognitive factor “theory of mind (ToM)” and the cognitive factors “cool” and “hot” executive function (EF).

Historical Background

Reciprocity in Children with ASD

Reciprocal behavior is pivotal to the process of collaborative behavior between individuals who

perform activities to reach shared goals (Cole and Teboul 2004). People who perform reciprocity successfully are aware of others' emotional and interpersonal cues, interpret those cues appropriately, respond suitably to what they interpret, and are motivated to engage in social interactions with others (Constantino et al. 2003). Reciprocity consists of mutual and symmetrical exchanges between individuals as they talk, work, or play together (Gernsbacher 2006). Such collaboration is a critical component of human social behavior, one in which we engage often in social contexts (Hammerstein 2003; Stevens and Hauser 2004). If people do not equally participate and exchange with fine turn-taking, collaboration will fail, leading to unsatisfactory results (Cole and Teboul 2004). A child's ability to perform reciprocal behaviors develops along with age, depending on both the child's cognitive ability and emotional functioning (Perez and Gauvain 2005). Therefore, reciprocity is an important skill for social interaction.

A study by Sakaiya et al. (2013) investigated the neural process of human reciprocity in social interactions with prisoner's dilemma (PD) games, which are used to examine cooperative behavior in adults. An important component of PD games is the Nash equilibrium, which represents mutual defection. Such equilibrium leads to lower payoffs for each player than does mutual cooperation and thus poses a dilemma. To investigate the neural correlates of reciprocal interaction, the researchers manipulated the partner identity (human, computer) and strategy (random, tit-for-tat) in the game. The results showed that, in the human-as-partner condition, tit-for-tat and random strategies were positively and negatively correlated with activation of the left amygdala. This activation represented positive feelings toward reciprocal partners and negative feelings toward nonreciprocal partners. That study also examined the neural process of insight into the reciprocity of partners. Reciprocity influenced differential brain activation in the reward-related circuitry (i.e., the right middle dorsolateral prefrontal cortex and dorsal caudate) and theory of mind (ToM) regions [i.e., the ventromedial prefrontal cortex (VMPFC) and precuneus]. In

participants without insight into their human partners, a tit-for-tat strategy led to asymmetrical activation in the precuneus and VMPFC and activation of the precuneus accompanied by the deactivation of the VMPFC. In summary, the amygdala processes the intensity of emotion in human reciprocity, and the reward-related and ToM regions control the insight into the reciprocity of others.

From infancy, children display motivation for engaging in joint actions and sharing psychological states with others (Carpenter 2009; Feldman and Greenbaum 1997; Trevarthen and Aitken 2001). At as early as 2 months old, mother-infant interactions involve looking at and listening to each other, mutually regulating one another's interests and feelings, exchanging multimodal signals, and imitating vocal, facial, and gestural expressions. During the course of early childhood development, a child's ability to collaborate with others develops from basic to more advanced levels. At around 2 years of age, children begin playing in proximity to each other, doing the same types of activities. In such so-called parallel activity, the children's attention is focused on the same object, but they operate it separately, without engaging in mutual exchanges. In essence, they are playing alone, rather than with other children (van Ommeren et al. 2012). Gradually, the children begin interacting with other children, exhibiting reciprocal behaviors such as equal turn-taking and object sharing (Eckerman et al. 1989; Warneken and Tomasello 2006). At 3 years of age, children begin sharing themes with their playmates, such as building a sandcastle together (Howes 1988). During middle childhood, when children begin to understand others' goals and intentions, they exhibit collaborative reciprocal behaviors. At this age, children have gained the requisite skills and motivation to share psychological states with others (Tomasello et al. 2005). This sharing behavior, which consists of basic to complex reciprocity, enables children to achieve common goals, such as building a small playhouse or drawing a picture (van Ommeren et al. 2012).

Previous studies have investigated the reciprocity ability of children with ASD. In the

study of Sally and Hill (2006), children with ASD and normal IQ were found to reciprocate adequately in a structured test; e.g., on a prisoner's dilemma task. However, adequate performance observed in a structured assessment does not necessarily carry over to real-life interactions. In unstructured real-life interactions, children with ASD are unable to show appropriate reciprocal behaviors with peers and adults. In the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, it is noted that children with ASD have qualitative impairment in social interaction, including failure to develop peer relationships; a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people; and a lack of social or emotional reciprocity (APA 2000). Ozonoff and Miller (1995) found that children with ASD have lower scores in the Socialization domain (which is correlated with reciprocity in daily life) of the Vineland Adaptive Behavior Scale (VABS). The studies of Kasari et al. (2011); Rotheram-Fuller et al. (2010); and Chamberlain et al. (2007) investigated the social networks and friendship reciprocity of children with ASD in elementary school. It was found that children with ASD have lower social network centrality and less friendship reciprocity than their typically developing peers do.

The social reciprocity deficit described above can lead to consequences for children with ASD. School-aged children and adolescents with ASD have increased risk of peer rejection and social isolation (Chamberlain et al. 2007). These children also express that they have less social support and more loneliness than typically developing children (Bauminger and Kasari 2000). The deficit may also lead to underachievement in academics and their later occupations (Howlin and Goode 1998). At the later stages of development, social reciprocity deficit may increase the risk of mood and anxiety problems (Myles et al. 2001; Tantam 2003).

However, the above evidence for this impairment is primarily based on observations of children in daily life, rather than direct assessments with psychological instruments (van Ommeren et al. 2012). Therefore, reciprocity performance

in the laboratory context is not correlated with social interactions in daily life.

Theory of Mind in Children with ASD

Theory of mind (ToM) has been used interchangeably with terms such as "perspective-taking," "social cognition," "metacognition," and "folk psychology." (Astington and Baird 2005; Flavell et al. 2002). ToM is a cognitive ability (Adolphs 2001) whereby a person understands and infers the mental states (e.g., belief, desires, and intentions) of others and uses that information to explain and predict behaviors and actions (Premack and Woodruff 1978; Wellman 1993). ToM assessment traditionally has relied on the false-belief task (Wimmer and Perner 1983), which identifies the ability to realize that people may have different or false understandings and representations of a given situation (Dennett 1978).

However, ToM is understood to be a complex and multifaceted construct. Some researchers have recommended that various aspects of ToM be assessed across levels of complexity (Tager-Flusberg 2001; Wellman et al. 2001) and suggested that it is constructed of related but distinct types of social cognitive understanding (Hughes et al. 2000), such as emotion recognition (Prior et al. 1990), desire-based emotion (e.g., understanding that people are happy when they get what they want), belief-based emotion (e.g., understanding that people will be happy if they think they will get what they want) (Baron-Cohen 1991), understanding that seeing leads to knowing (Perner et al. 1989), and understanding that people see the same object in different ways (e.g., by positioning) (Pillow and Flavell 1986). Complex, or higher-order, ToM is typically measured with a second-order false-belief task (e.g., what Wendy thinks Patty thinks) to assess inferences of both belief and emotion (Hughes et al. 2000).

ToM is a prerequisite skill for developing reciprocal communication and social interactions (Wellman 1990). It helps people understand and distinguish emotional states and complex social information. This ability also helps children to develop more complicated social cognitive skills,

such as perspective-taking, collaboration, and metacognition (Sally and Hill 2006).

Infants display some behaviors that are important beginnings for theory-of-mind development. By 2–3 months, they are able to participate in simple social interactions with others and can coordinate their gestures, vocalizations, and facial expressions with others (Mar et al. 2010). By the age of 2, children clearly show awareness of the difference between thoughts in the mind and things in the world (e.g., pretending a block is a car) (Kavanaugh 2006). They also understand belief-based emotion (e.g., people will feel happy if they get what they want) (Wellman and Banerjee 1991). A crucial development occurs at around 4 years of age, when children realize that thoughts in their minds may not be true. At age 4 or 5, children develop the ability to understand a first-order false-belief task (Wimmer and Perner 1983), and they realize that people talk and act on the basis of the way they think the world is, even when their thoughts do not reflect the actual situation. After 5 years old, children develop advanced mental understanding, such as second-order false-belief, lies, and metacognition (Astington and Gopnik 1991).

Many researchers have concluded that ToM deficits underlie the social, behavioral, and communicative impairments in individuals with ASD (Baron-Cohen et al. 1985). The most common ToM assessment is the classic false-belief task, originally developed by Wimmer and Perner (1983). In this task, children are told a story in which an object is moved from an old location to a new location without the knowledge of the main protagonist. The children are asked, “Where would the main protagonist look for the object?” The old location is the correct answer. As compared with age- and language-matched peers, individuals with ASD generally perform poorly on the false-belief task.

In a study by Baron-Cohen et al. (1985), the Sally-Anne task (first-order false-belief task) was used to examine ToM in children with ASD, and fewer individuals with ASD (20%) passed the test than did typically developing children (85%). In Baron-Cohen (1989), a second-order false-belief task was used to examine ToM in

children with ASD. In that study, none of the children with ASD passed, while 90% of the typically developing children did. In addition, children with ASD are reported to have difficulties in using logic, inferring beliefs, and recognizing emotions (Prior et al. 1990).

In Baron-Cohen (1991), the researchers examined whether individuals with ASD understand some causes (situations, desires, beliefs) of emotions. They found that children with ASD showed deficits in the comprehension of emotions caused by belief as compared with mental age-matched peers. In summary, children with ASD show deficits in both higher-level and lower-level ToM tasks.

Executive Function in Children with ASD

According to Lezak (1995), “Executive functions refer to a collection of interrelated cognitive and behavioral skills that are responsible for purposeful, goal-directed activity, and include the highest level of human functioning.” This collection encompasses the ability to suppress responses, to keep and manipulate information online, to change strategies, and to plan ahead. Executive function allows people to access information, think about solutions, and implement those solutions.

Nowadays, EF is divided into cool and hot aspects. Cool executive function (Cool EF) is defined as goal-directed and future-oriented skills manifested within abstract, decontextualized, nonemotional, and analytical conditions. It is a more purely cognitive aspect of EF usually associated with the dorsolateral prefrontal cortex (DLPFC) (Metcalf and Mischel 1999). Hot executive function (Hot EF) is defined as goal-directed and future-oriented cognitive processes manifested within the contexts of engendering emotion and motivation (Zelazo and Carlson 2012; Zelazo and Müller 2002; Zelazo et al. 2005). It is the affective aspect of executive function and is usually associated with the orbital frontal cortex (OFC) and other medial regions (Happaney et al. 2004).

Despite the numerous investigations of cool executive function in children with ASD, the results have been inconsistent (Geurts et al.

2009; Hill 2004). Some studies have indicated that children with ASD have difficulties in tasks requiring working memory, inhibition, and set shifting ability as compared to their typically developing peers (Hughes et al. 1994; Szatmari et al. 1989), while others have cast doubt on those findings.

Recent studies have found that EF performance is affected by the age of the participants. Older children and adults score worse than their mental age-matched peers, while younger children with ASD exhibit no impairments as compared to their peers (Dawson et al. 1998; McEvoy et al. 1993; Yerys et al. 2007). It is suggested that executive function deficit may not be the primary deficit in children with ASD; rather, it may be a secondary one that manifests as the children develop (Yerys et al. 2007).

Some researchers have suggested that autism and related disorders may involve deficits in global processing and social and emotional functioning (i.e., hot EF) (Happaney et al. 2004), which are controlled by the right and left VMPFC hemispheres. Bechara (2004) suggests that the differential involvement in the right and left hemispheres in avoidance (negative affect) and approach (positive affect) lead to right–left hemispheric asymmetries in the OFC (VM-PFC) (Davidson and Irwin 1999; Davidson et al. 2000). For example, the Iowa Gambling Task requires adaptive decision-making, for seemingly positive responses need to be avoided (a function for which the right VM-PFC may be particularly well suited). The right hemisphere has also been implicated in the mapping of bodily states and the comprehension of somatic information (Cohen et al. 1976), which may help to explain the relative importance of the right OFC in hot EF (Bechara 2004).

Based on a previous literature review on reciprocity, it appears that EF and ToM are important factors in reciprocity in children with ASD. When directly examining the relationships between ToM and reciprocity in children with ASD with the behavioral approach, Sally and Hill (2006) found that children with ASD have impaired ToM ability in both first- and second-order false-belief tasks as compared to their typically developing peers, but

the results for reciprocity in games did not show significant group differences. As explanation, the authors suggested that ToM skills may not be needed in structured computer games. Examinations of the relationships between EF and reciprocity in children with ASD with the behavioral approach have identified the neural correlates of reciprocity (Sakaiya et al. 2013). The DLPFC and VMPFC are active during reciprocal behaviors. Cool EF, controlled by the DLPFC, may affect reciprocity performance. However, no behavior studies have directly investigated the relationship between cool EF and reciprocity in children with ASD. Hot EF, which is controlled by the OFC, one part of the VMPFC, may affect reciprocity performance.

Current Knowledge

ToM and cool EF have been used to explain social deficits. In addition, the brain regions controlling ToM and EF appear to be the neural correlates of reciprocity in children with ASD. However, these two theories, ToM and cool EF, cannot fully explain reciprocity in children with ASD, possibly due to a lack of consideration of the importance of motivation and emotion. To date, only the behavioral study of Lai and her colleagues has examined ToM and EF simultaneously in the reciprocity in children with ASD. In Lai et al.'s study, a total of 59 children with diagnoses of autistic disorder or Asperger's syndrome aged from 4 to 12 years were recruited. In addition to the children's verbal ability and autistic severity, their reciprocity (van Ommeren et al. 2012), ToM, cool EF, and hot EF were examined with the Interactive Drawing Task (IDT), Theory of Mind Task Battery (Hutchins et al. 2012), Dimensional Card Change Sort Task (DCCS) (Diamond and Kirkham 2005; Dichter et al. 2010), and Children's Gambling Task (Kerr and Zelazo 2004).

The IDT was specifically used in Lai et al.'s study to measure children's reciprocity performance (van Ommeren et al. 2012). The IDT is designed to examine reciprocity in a joint, unstructured situation to re-create the unstructured, unpredictable aspects of real-life social

interactions. During the IDT, children are invited to draw a house with the experimenter. Requiring no real drawing skill, the test elicits spontaneous interaction with the experimenter to achieve a mutual goal. The IDT lasts approximately 10 min and requires only a table, drawing paper of size A3, four colored markers (red, blue, black, green), and a video camera. At the beginning of the test, the experimenter says, “We are going to draw together. You may choose a marker.” No other instructions are provided. The goal of the IDT is to elicit equal participation of the participants, with the experimenter setting a good example of how to collaborate with others. To do so, the experimenter performs reciprocal behaviors with increasing dynamics, such as beginning to draw his or her own objects and contributing to the child’s objects. The experimenter also elicits reciprocal behaviors by drawing incomplete objects and by demonstrating reciprocal responses, such as adding elements to an incomplete drawing by the child. Then the experimenter encourages turn-taking by turning the paper to the child, an action that is repeated throughout the test. This assessment measures three types of reciprocal behaviors. The first is the proportion of reciprocal drawing (i.e., collaborating by adding meaningful elements) of the total turns, or total reciprocity. Reciprocal drawing (total reciprocity) is divided into the proportion of reciprocity in the other’s initiative and reciprocity in the child’s own initiative. The former is the amount of reciprocity in the objects drawn by the experimenter, and the latter is the amount of reciprocity in those drawn by the child.

By measuring reciprocity, ToM, hot EF, and cool EF, Lai et al. showed that cool EF and hot EF are both significantly correlated with reciprocity and that in children with ASD, only verbal ability is significantly correlated with reciprocity in the child’s own initiative.

In Lai et al.’s study, cool EF and hot EF were significantly correlated with reciprocity in children with ASD. They also found that cool EF was the significant correlate for reciprocity in the child’s own initiative. However, none of the variables in their study were significantly associated with reciprocity in the other’s initiative.

Therefore, children with better cool EF and hot EF may have better reciprocity capacity and reciprocity in the child’s own initiative. However, the correlate of reciprocity in the other’s initiative was not identified in their study, so the correlates of children’s reciprocity in the other’s initiative remain undetermined.

In addition, Lai et al.’s study found that cool EF and hot EF may be the significant correlates of reciprocity. Children with better cool EF and hot EF ability may perform more reciprocal behaviors. Another important result was the significant correlation between cool EF and reciprocity. The cool EF task, the DCCS, focuses on children’s ability to shift attention. Children who can correctly shift their attention based on the sorting rule may perform more reciprocal behaviors because they can more easily shift their attention to the collaborative theme. This conclusion is consistent with neural process research reporting that the neural correlate of reciprocal behaviors is the DLPFC, the neural region for cool EF (Sakaiya et al. 2013). Hot EF, however, is a goal-directed and future-oriented cognitive process, manifested within the contexts of engendering emotion and motivation (Zelazo and Carlson 2012; Zelazo and Müller 2002; Zelazo et al. 2005). It appears to be significantly associated with the capacity for reciprocal behavior. It is possible that the IDT requires that motivation be maintained; if so, the importance of the drawing themes may need to be reappraised. Children with better hot EF ability, having the ability to keep their attention and motivation focused on the reciprocal themes, can contribute meaningful elements toward the collaborative goals.

The nonsignificant relationship between ToM and reciprocity reported by Lai et al. may have two possible explanations. The first is the obvious nature of the drawing theme of the experimenter. The children may not have needed to employ ToM to speculate on the experimenter’s behaviors. The second is the lack of structure and unpredictability of the IDT. Faced with this unstructured situation, the children with ASD might have found it difficult to generalize their ToM ability to it and thus been unable to respond properly. Despite being able to perform well on the ToM task, the

unstructured context may have limited their ability to perform well on the reciprocity task. This explanation is consistent with findings that, in an unstructured context, children with ASD have difficulties applying their ToM. High-functioning adolescents and adults with ASD can pass ToM tasks at various levels of complexity (Dahlgren and Trillingsgaard 1996). In structured situations, they can respond properly (Begeer et al. 2010), but in unstructured and unpredictable situations, they cannot. However, Tomasello et al. (2005) found that children with ASD have fewer reciprocal behaviors, possibly due to difficulties in understanding others' intentions. This finding is inconsistent with the nonsignificant correlation between ToM and reciprocity of Lai et al.'s study. In summary, the relationship between ToM and reciprocity needs to be further clarified, and the task characteristics, such as the collaborative themes and unstructured or structured tasks used in measuring children's reciprocal behaviors and social interaction, also need to be considered.

As for reciprocity in the child's own initiative and reciprocity in the other's initiative, the present literature suggests that children with ASD present more reciprocity in their own initiative than in another's initiative. It is possible that their restricted behaviors interfere with their ability to shift their attention to another's drawing theme. For instance, in Lai et al.'s study, many of the participants focused on drawing dinosaurs, cars, and busses; they had a hard time following the experimenter's initiative. Another study, van Ommersen et al. (2012), also suggested that children with ASD preferred to lead the drawing themes because they wanted to avoid the confrontation of unexpected situations. To do so, they would perform more reciprocity on their own initiatives.

In addition, children's reciprocity performance on the IDT can be divided into three types: active, passive, and proper reciprocity. Children exhibiting active reciprocity present much reciprocity in their own initiatives and draw typical objects such as cars and busses. Like younger children diagnosed with Asperger's syndrome, these children show only limited responses to the experimenter's initiatives. Children exhibiting passive reciprocity respond well to the

experimenter's initiative, following the experimenter's drawing theme. However, these children rarely initiate their own drawing themes, depending on the experimenter to lead them. Children exhibiting proper reciprocity balance their responses to their own initiatives and to the experimenter's initiatives. They take turns with the experimenter in assuming the leading role, so the dynamic between the experimenter and the child is relatively high.

These types of reciprocal behaviors on the IDT are fairly consistent with the four types of social interaction styles (Castelloe and Dawson 1993; O'Brien 1996; Scheeren et al. 2012): typical, active-but-odd, passive, and aloof. The active type of IDT performance, wherein the children develop their own drawing themes but fail to respond properly to the experimenter's, is similar to the behaviors of active-but-odd children. These children seek out social interaction but do so in an unusual way, such as holding one-sided conversations about their own interests. The passive type of IDT performance, in which the children seldom initiate their own drawings but add proper, meaningful elements to the experimenter's, is similar to the behaviors of passive children. These children do not initiate social interaction, but they respond appropriately to another's initiative. The proper type in IDT performance, wherein the children both initiate their own themes and participate in the experimenter's, resembles the behaviors of typical children, who act properly in social interactions. The absence of any reciprocity on the IDT thus may resemble the behaviors of aloof children, who neither seek out social interaction nor respond to another's initiative. This can be expected, since such children usually have less verbal ability and are low-functioning. Considering the similarities between the types of IDT performance and social interaction styles, an important correlate of reciprocity in the child's own or another's initiative may be the children's social interaction styles.

In conclusion, children with ASD who have better cool EF and hot EF may have better reciprocity capacity, which can be used as the basis for targeting interventions and as the foundation for further study. For clinicians, it is necessary to

focus evaluations and interventions on cool EF and hot EF. With such measurement, clinicians could understand the children's cool EF, hot EF, and reciprocity and thereby detect progress after interventions. Based on the evaluations, interventions targeting cool EF and hot EF could be provided to improve the children's reciprocal behaviors. Targeted interventions could be accordingly developed and provided to children with ASD to improve their reciprocity.

Future Directions

At this stage, the current existing findings cannot be generalized to lower-functioning and nonverbal children with ASD, and their social interaction styles have not been assessed. Future studies should consider recruiting lower-functioning children and those with less verbal ability, use corresponding measurements adjusted for these children, and add a measurement for evaluating social interaction styles. In addition, as regards the relationship between ToM and reciprocity, further study is warranted to better elucidate the relationship between ToM and reciprocity with consideration of the task characteristics, such as the collaborative themes and unstructured or structured tasks used in measuring children's reciprocal behaviors.

Cognitive Enhancement Therapy

Shaun M. Eack

School of Social Work and Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

CET; Cognitive rehabilitation; Cognitive remediation; Social cognition training

Definition

Cognitive Enhancement Therapy is a comprehensive cognitive rehabilitation intervention designed to improve the social and non-social cognitive impairments that limit adaptive function and quality of life in certain neurodevelopmental disorders. The treatment integrates computer-based cognitive remediation exercises in attention, memory, and problem-solving with a small group-based social cognitive training curriculum designed to improve perspective-taking, social context appraisal, emotion perception and management, and other key aspects of social cognition. Through these integrated activities, Cognitive Enhancement Therapy addresses the core neurocognitive and social cognitive deficits experienced by verbal adults with autism spectrum disorders.

Historical Background

Cognitive Enhancement Therapy (CET) was developed in the 1990s by Professor G. E. Hogarty for the treatment of social and non-social cognitive impairments in schizophrenia. The development of CET was influenced by the holistic cognitive rehabilitation approach of Ben-Yishay et al. (1985) for individuals suffering from a traumatic brain injury, as well as Brenner's (2000) *Integrated Psychological Therapy* for

schizophrenia. During the late 1990s and early 2000s, Hogarty and colleagues conducted a series of research studies supported by the National Institute of Mental Health that developed CET, established its evidence base for patients with schizophrenia and schizoaffective disorder (Hogarty et al. 2004; Eack et al. 2009), and created a comprehensive treatment manual outlining the methods of the approach (Hogarty and Greenwald 2006). A key finding from these studies was that CET could not only improve core social and non-social cognitive impairments in schizophrenia but that its early application could protect against brain loss and support gray matter growth in areas of the brain involved in social cognitive information processing (Eack et al. 2010b).

The positive findings of CET in schizophrenia led the investigators and other researchers to consider the potential applicability of the intervention to other disorders that are characterized by core deficits in information processing and social cognition. Autism spectrum disorders were viewed as primary candidates due to their chronic and debilitating nature, the presence of pervasive impairments in social and non-social cognition, and lack of available interventions for adults. The many similarities between autism and schizophrenia had led classic psychiatric nosologists to characterize the disorders within the same diagnostic category. Although the categorizing of autism with schizophrenia was ultimately found to be inaccurate, due to sharp distinctions relating to the presence of psychosis and age of onset, evidence continues to highlight that both disorders are similarly affected by marked impairments in neurocognitive and social cognitive function (Goldstein et al. 2002; Velikonja et al. 2019), which may reflect similar pathophysiologic processes (Pinkham et al. 2007). Such findings provide early support for the applicability of CET to adults with autism spectrum disorders.

In 2009, CET investigators S. M. Eack, D. P. Greenwald, and S. S. Hogarty began collaborating with autism expert N. J. Minshew at the University of Pittsburgh to adapt and conduct the initial feasibility studies of CET in autism. With early support from the National Institute of Mental

Health and the Pennsylvania Department of Health, CET treatment materials were successfully adapted from schizophrenia to verbal adults with autism spectrum disorders. In addition, an uncontrolled feasibility study was completed to assess the acceptability of the intervention in autism and measure initial levels of efficacy. As expected, CET proved to be highly applicable to adults with autism and satisfying and acceptable to recipients. Subsequently, a first randomized controlled trial was conducted at the University of Pittsburgh to examine efficacy and establish the evidence base for CET in verbal adults with autism spectrum disorders, which indicated significant improvements in cognitive function and employment in adults with autism treated with the approach (Eack et al. 2018).

Underlying Theory

The underlying theoretical framework for CET relies upon a neurodevelopmental model of schizophrenia (Hogarty and Flesher 1999), which may be applicable to other conditions, such as autism. Neurodevelopmental models situate the core disease process in mental and neurological conditions within the brain, and impairments in brain development and function result in core deficits in cognitive functioning that lead to social and vocational disability. Consistent with neurobehavioral models of autism (Minshew and Goldstein 1998), genetic alterations result in early brain abnormalities that affect the development of neural systems responsible for supporting the acquisition of higher-order social cognitive abilities. CET is a developmental approach in that it aims to facilitate cognitive development by shifting reliance from early and effortful serial cognitive processing to a gistful and spontaneous abstraction of social themes needed for effective interpersonal interaction.

The treatment methods employed in CET find their theoretical basis in models of brain plasticity and sociological theories of secondary socialization. The ability of the brain to be shaped, at even a basic molecular level, by environmental experiences has been well-established and is known as

neuroplasticity (Buonomano and Merzenich 1998). Strategic practice of cognitive exercises that activate different brain systems has been shown to enhance brain function, synaptic connections, and cortical organization (Bryck and Fisher 2012). CET builds on this evidence to provide adults with autism the opportunity to engage in targeted cognitive exercises and experiences designed to enhance brain functions associated with improved social and non-social cognition. The enhancement of social cognition is an essential goal of CET and relies on the sociological principles of secondary socialization, where individuals must develop the ability to abstract informal rules for behavior from appraising the context of unrehearsed social situations. Children are initially socialized using primary socialization methods that focus on direct instruction, usually from parents and teachers (e.g., “use your napkin,” “don’t hit your sister,” “wait until it’s your turn”). However, as the complexity of their social world expands, rigid rules for behavior become less useful, and there is a need for cognitive flexibility in socialization that recognizes the fluidity of adult interactions. Further social cognitive development must utilize secondary sources of information to guide behavior, such as observing the social context and understanding the perspective of others. The development of these abilities is a key aspect of the social cognitive curriculum in CET, which are practiced within a small group context.

Goals and Objectives

The overall goal of CET is to enhance neurocognitive and social cognitive functioning as a method of improving social adjustment, adaptive function, and quality of life. This is achieved through targeting of two broad goals in the treatment. The first goal is to foster higher-order thinking among CET participants. The emphasis in CET is on helping individuals learn to shift from an earlier, pre-adolescent cognitive style of processing that is characterized by passivity, concreteness, rigidity, and rehearsal to a more adult style of information processing that is active,

abstract, flexible, and spontaneous. The second goal is to help individuals develop “social wisdom” or the ability to act wisely in social situations, not by learning and rehearsing scripted rules for behavior but by developing the social cognitive abilities that allow for an accurate assessment of and response to spontaneous interpersonal interactions. To accomplish this, individuals learn how to appraise different social contexts and identify the related rules and norms for behavior; take the perspective of others to understand their feelings and intentions; be foresightful in responding to social situations; acknowledge and participate in the reciprocal nature of social interactions; and ultimately develop a greater level of social comfort. These two goals serve as a guiding foundation for all activities in CET and are actively addressed during both neurocognitive training and social cognitive group sessions.

Treatment Participants

Treatment experiences in providing CET to adults with autism spectrum disorder indicate that many individuals with these conditions are likely to benefit from the intervention. Adults with autism have many strengths that they bring to CET, and the goal is to build on these strengths to help improve adaptive function and quality of life. The treatment is applicable to verbal adults with autism spectrum disorder who have an $IQ \geq 80$ and experience significant social and cognitive disability. Currently, CET treatment materials are only available in the English language, and thus proficiency with English is also important. Individuals unlikely to benefit from CET include those with significant intellectual disabilities ($IQ < 80$), individuals who have not developed language skills, and individuals with an organic brain syndrome, substance use problems, persistent suicidality, or disruptive behaviors not conducive to a group context. Individuals with autism commonly experience comorbid psychiatric conditions, such as anxiety or depression, and as long as these conditions are stabilized and managed appropriately, individuals with these conditions may still benefit from CET.

Treatment Procedures

Cognitive Enhancement Therapy integrates 60 h of computer-based neurocognitive training in attention, memory, and problem-solving with 45 1.5 h weekly social cognitive group sessions provided over the course of 18 months. Treatment begins with a thorough assessment of the participant’s cognitive and social difficulties. Subsequently, participants begin neurocognitive training in attention. Neurocognitive training contains three sequential modules: an attention module, a memory module, and a problem-solving module. Attention training focuses on increasing processing speed, sustaining attention, inhibiting irrelevant stimuli, and shifting attention. Memory training focuses on developing a categorizing capacity, cognitive flexibility, and the ability to abstract and recall the “gist” or main point from information to be remembered. Finally, problem-solving training focuses on improving foresightfulness and planning, reasoning, and executive functioning, and it both relies upon and reinforces the attention and memory abilities gained in previous modules. Unlike other cognitive remediation programs, participants in CET receive neurocognitive training in pairs, which affords opportunities for socialization and to begin learning important early aspects of social cognition, such as giving support. Neurocognitive training is facilitated by a therapist “coach” who promotes strategic thinking about how to complete a given exercise and integrates key CET concepts into the sessions, such as managing emotions, gistful processing, working memory, cognitive flexibility, and foresightfulness.

After approximately 2–3 months of attention training, 3–4 participant pairs (6–8 participants) form a small social cognitive group. The emphasis of these weekly social cognitive group sessions is on enhancing social comfort and the abilities needed for effective socialization, interpersonal interactions, and successful adjustment to adult life. All group sessions follow a highly structured format that allows for spontaneity but also keeps the group process predictable and efficient. Each group session begins by distributing an agenda along with handouts for the psychoeducational

lecture for the day. Participants are then asked to present their homework assignment based on the previous week's lecture, and homework presentations are chaired by one of the group members, who asks the members to volunteer to present their homework. The chairperson role is designed to facilitate working memory, organization, and cognitive flexibility. After the homework presentation is finished, select participants complete an in-group cognitive exercise designed to enhance social cognition. Exercises are usually performed in pairs and require participants to practice the social cognitive abilities they are learning in the group, such as perspective-taking, social context appraisal, gistfulness, and reading nonverbal cues. The group members who are not actively completing the exercise are asked to give feedback to their peers on their performance. This important task promotes observational skills and engagement for group members and provides the opportunity to give support and practice giving appropriate feedback in an organized, constructive way. Finally, a psychoeducational lecture is given on a new topic on social cognition, and homework is assigned to facilitate application outside of the group setting.

A broad number of social cognitive topics are covered throughout the 45 group sessions and include perspective-taking, emotion perception, stress management, understanding the social "gist", giving support, reciprocity, and social context appraisal among others. The goal is to provide participants with the core social cognitive abilities they need to succeed in reaching their goals, build better relationships, and communicate and interact effectively with others. Neurocognitive training proceeds concurrently throughout the time individuals are also participating in the social cognitive groups, until the completion of all attention, memory, and problem-solving computer exercises. A complete descriptions of the original treatment methods and procedures used in CET are outlined in detail in *Cognitive Enhancement Therapy: the Training Manual* by Hogarty and Greenwald (2006), and adaptations specific to adults with autism spectrum disorders are forthcoming in a supplement to this treatment manual.

Efficacy Information

The development of CET for individuals with schizophrenia was supported by the National Institute of Mental Health, and primary data regarding its efficacy comes from two randomized controlled trials with individuals with schizophrenia and schizoaffective disorder. Effects of CET on neurocognition and social cognition in both of these studies were large (range of $d = 0.58$ – 3.09), and effects on functional outcome and social adjustment were also highly significant and large (range of $d = 1.40$ to 2.59) (Hogarty et al. 2004; Eack et al. 2009). Further, mediator analyses from these studies indicated that the benefits CET had on cognition were significant contributors to the improved adjustment and adaptive function of participants (Hogarty et al. 2006; Eack et al. 2011). Evidence of the durability of these effects have also been positive, with studies indicating that the effects of CET on cognition and functioning can be maintained for at least 1 year post-treatment (Hogarty et al. 2006; Eack et al. 2010a). Finally, evidence has indicated that CET has a direct effect on the brain, in that it can protect against gray matter loss and even result in increased levels of gray matter in social cognitive brain networks when applied in the early course of schizophrenia (Eack et al. 2010).

Efficacy information on CET effects specific to the autism population is now available, with the completion of the first randomized controlled trial of this intervention in verbal adults with autism spectrum disorder supported by National Institute of Mental Health, Department of Defense, and Autism Speaks (Eack et al. 2018). This 18-month clinical trial randomized 54 verbal adults with autism with $IQ \geq 80$ to either CET or an enriched supportive therapy (EST) comparison condition that focused on education about autism and stress and condition management. The study included an active comparison condition to CET for two reasons. First, the availability of psychological treatments in routine care for adults with autism is quite limited, reducing the feasibility of a study of CET compared to "treatment as usual." Second, EST includes many of the nonspecific components of CET (e.g., provision of a skilled

emphatic therapist, psychoeducation), and comparison of CET to EST provided a particularly stringent test as to whether the specific cognitive training components in CET could result in improved cognitive and functional outcomes in adults with autism.

Results from this first controlled trial indicated significant and medium-sized ($d = 0.46$, $p = 0.013$) effects on non-social cognition favoring CET compared to EST, particularly in speed of processing, which evidence indicates is one the most affected areas of non-social cognitive function in the condition (Haigh et al. 2018; Velikonja et al. 2019). Effect sizes of CET on non-social cognition over 18 months were medium-to-large in magnitude ($d = 0.76$) compared to EST ($d = 0.31$), which also showed some benefits to non-social information processing. With regard to social cognition, individuals treated with CET demonstrated large improvements ($d = 0.89$), particularly in blind-rated clinical assessments of social cognitive behaviors, as well as domains of emotion perception and management. Interestingly and unexpectedly, individuals treated with EST also evidenced significant and medium-to-large levels of improvement in social cognition ($d = 0.62$) after 18 months of treatment. Differential effects on social cognition clearly favored CET by mid-treatment (9 months) ($d = 0.58$, $p = 0.020$); however the advantage of CET compared to EST for improving social cognition was not maintained by the completion of 18 months of treatment ($d = 0.27$, $p = 0.298$). Such findings were not the result of a loss of social cognitive gains in those treated with CET but a larger than expected improvement in this domain during the second half of treatment among individuals receiving EST. We concluded that while CET appears uniquely effective for addressing non-social cognitive impairments in adult autism, both interventions may have important benefits to social cognition, with CET providing a more rapid treatment response in this domain than EST.

The cognitive gains associated with CET observed in this first trial were hypothesized as key mechanisms for supporting improved functional outcomes in verbal adults with autism

spectrum disorder. When examining the efficacy of CET compared to EST on functional outcomes, clear gains in non-sheltered competitive employment were observed in participants treated with CET that were not evident in those who received EST. Overall, individuals receiving CET were nearly 6 times more likely to become competitively employed during the 18-month trial than their EST counterparts ($OR = 6.21$, $p = 0.005$), indicating the benefits of cognitive rehabilitation to important functional outcomes in this population. Furthermore, improved social and non-social cognition significantly predicted competitive employment outcomes and were partial mediators of the impact of CET on employment, supporting hypotheses that the treatment of cognitive impairments in adults with autism is a productive avenue for enhancing functioning and reducing disability. Given the initial nature of this first trial and its modest sample size, a randomized confirmatory efficacy trial supported by the National Institute of Mental Health is now underway with a larger set of participants to determine whether these effects can be replicated. In addition, follow-up studies 1 year after treatment are being conducted to determine what gains can be maintained once treatment is completed.

Outcome Measurement

Outcome assessment is important in CET to guide clinician behavior and provide feedback on success to participants. Several outcome measures are included in the CET programs that are easy to complete by participants and clinicians and provide a sensitive metric upon which to gauge progress. The attention training software utilized in CET developed by Ben-Yishay et al. (1985) contains a simple reaction time assessment of processing speed, and it is recommended that clinicians utilize this assessment before beginning attention training and every 9 months thereafter until the completion of treatment. Two interview-based assessments, the Social Cognition Profile and the Cognitive Styles Inventory (Hogarty et al. 2004), provide assessments of both

neurocognitive and social cognitive improvement during treatment. It is recommended that these assessments be administered to participants prior to beginning treatment and every 9 months thereafter. These standardized assessment instruments will provide both clinicians and participants with a greater understanding of the cognitive strengths and limitations of the participant and his/her degree of improvement during CET.

For clinics and programs that have access to neuropsychological testing materials, several standardized assessments are useful, but not required for judging progress in CET. These include the revised Wechsler Memory Scale, Wisconsin Card Sorting Test, Trails B, and the California Verbal Learning Test. In addition, the Mayer-Salovey-Caruso Emotional Intelligence Test (Mayer et al. 2003) has proven to be an effective assessment of components of social cognition during CET and is self-administered through a computer. Information from these assessments can be useful for treatment planning, as well as examining progress.

Qualifications of Treatment Providers

Qualified providers of CET are not limited to a single profession. In research studies on CET, individuals from many different backgrounds and disciplines have been successfully trained to provide the treatment. This has included social workers, psychologists, and psychiatric clinical nurse specialists, all of which make up the primary workforce who serve adults with autism spectrum disorders. The critical qualifications for providing CET include education in a human service profession (preferably at a master's level), experience (2 or more years) in the treatment of verbal adults with autism or similar conditions, a willingness to resist a traditional psychotherapeutic approach, and an eagerness and commitment to learn new approaches to intervention.

The methods and intervention approaches employed in CET are novel and likely to be different from any treatment approach clinicians have provided before to adults with autism.

Consequently, beyond having the requisite educational and work experience in order to be knowledgeable about the treatment of autism, it is of utmost importance that potential providers are open and willing to learn a new approach. Some providers become comfortable with certain techniques and have considerable difficulty when a new treatment requires them to deviate from their usual practices. In this way, effective CET clinicians must be cognitively flexible themselves, so that they can open up to new ways to help persons with autism. Clinicians that are uncomfortable with deviating from a traditional psychotherapeutic stance where they provide the instruction and advice to solve the problems for their patients (instead of helping the individual learn to solve their own problems) will have difficulty becoming an effective CET coach.

Finally, it should be noted that a qualified clinician is not enough to provide CET. Group sessions are conducted with a minimum of two qualified clinicians, which significantly enhances the process by introducing a greater diversity of ideas and insights into how to help participants. In addition, the feasibility of implementing CET without strong administrative and supervisory support is limited. As with all successful intervention programs, a commitment is required by clinicians and the agency to invest the necessary resources, training, and time to provide this comprehensive approach. The training required to learn CET is extensive and ongoing, making a strong commitment from the agency essential to successful implementation. In summary, CET is an innovative intervention that holds promise for improving adaptive function and lives of verbal adults with autism spectrum disorders.

Synonyms

[Cognitive shifting](#); [Mental flexibility](#); [Set shifting](#)

Definition

Cognitive flexibility refers to the cognitive function of adaptively shifting mental actions and behaviors based on feedback from the environment. It is a dimension of executive functioning, which is considered to be impaired in many people with autism spectrum disorders (ASD). Executive functioning refers to a broad category of

complex or higher-order cognitive skills that is crucial for organizing and selecting relevant information, planning responses, and executing actions. Compromised cognitive flexibility in ASD may contribute to challenges with appropriately adapting to changes in interpersonal and environmental demands (e.g., social situations). Difficulty switching problem-solving strategies or adapting responses in the face of situational changes characterize the experiences of people with ASD and can be explained by impairments in cognitive flexibility. Some evidence suggests that cognitive flexibility predicts social outcomes in ASD. Better performance on cognitive flexibility measures alone predicted greater improvement in scores of social competence over time in high-functioning adolescents and adults with ASD (e.g., Berger et al. 2003).

Studies assessing cognitive flexibility and related functions in ASD have found moderately robust findings of impaired flexibility, but not without mixed results. Card sorting tests, such as the Wisconsin Card Sorting Test (WCST; Heaton et al. 1993), are one type of neuropsychological assessment that have been sensitive to measuring aspects of executive functioning, particularly cognitive flexibility. Several aspects of impaired cognitive flexibility in ASD have been identified, yet these factors have yet to be uniformly observed across studies. In one study, high-functioning adolescents with ASD performed significantly poorer on the WCST in maintaining their cognitive set (a set of mental plans or rules deduced from direct feedback) relative to a typically developing control group (Kaland et al. 2008). No other significant differences in performance such as perseverative errors (repeatedly using a previously successful strategy despite feedback that it is no longer effective) were observed. Other studies using the WCST have demonstrated that perseverative errors are more common in individuals with ASD (e.g., Shu et al. 2001) as well as poorer performance on the total number of errors, completion of categories, and number of trials required to complete a category relative to control groups (e.g., Pennington and Ozonoff 1996). A lack of uniform findings indicates that cognitive flexibility is complex and multidimensional. It is

likely affected by various factors related to cognitive and executive functioning, explaining the variations in cognitive flexibility observed across the ASD population.

Definition

The term “cognition” refers to mental processes or forms of information processing. These processes include attention, memory, learning, decision making, reasoning, and problem solving. In the study of autism, a distinction often is drawn between social and/or nonsocial forms of cognition given the presumed centrality of social deficits to the disorder. Some also consider language to be a cognitive domain. The focus of this entry, however, is on cognition that is not explicitly social or language related. For more extensive discussions of social cognition and language, the reader is referred to other definitions in this encyclopedia.

Historical Background

Cognition is a term that became very popular in psychology with the onset of the “cognitive revolution” in the 1950s. This “revolution” resulted from the advent and use of computers. Academic psychology borrowed computer and artificial intelligence information processing concepts and

used them to derive testable hypotheses related to human thought processes. This new field, “cognitive psychology,” had a large impact on the larger discipline of psychology and replaced behaviorism as the dominant paradigm. Rapidly advancing fields of neuroscience, social psychology, and developmental psychology also began to influence the larger field of psychology. This resulted in the genesis of cognitive neuroscience, which seeks to understand the neural and other biological mechanisms underlying thought; social cognitive neuroscience, which employs findings from social psychology and attempts to understand their neurobiology; and developmental cognitive neuroscience, which examines the neurobiology of development in an effort to explain typical and atypical growth and development.

Current Knowledge

Many researchers, writing from different perspectives, have arrived at the conclusion that individuals with ASD exhibit a curious set of cognitive strengths and challenges. For example, Minshew and colleagues (Minshew et al. 1997) articulated the point of view that ASD involves spared simple information processing in domains of motor functioning, memory, language, and reasoning, with selective impairment in complex information processing, not involving visual-spatial processing, across these domains. They went on to argue that “this profile is not consistent with a single primary deficit, but with a multiple primary deficit model in which the deficit pattern within and across domains is reflective of the complexity of the information processing demands. This neuropsychological profile is furthermore consistent with the neurophysiologic characterization of autism as a late information processing disorder with sparing of early information processing.” This way of conceptualizing autism also has been extended to the neuroscience of autism. Here, autism has been portrayed as a disorder involving reduced functional connectivity (synchronous activity) between brain regions and neural circuits (Just et al. 2004), resulting in reduced synchrony among cortical regions supporting higher

cognition. Three important topics in higher cognition in ASD are discussed below.

Cognitive Level and IQ in ASD

First, it is important to provide background about cognitive ability level in ASD because it profoundly influences performance in areas of higher cognition, as well as multiple areas of functioning. The study of cognitive abilities in ASD also has attracted considerable research because the patterning of intellectual strengths and challenges in persons with ASD may be very different than that present in typically developing individuals, and this has clear implications for education and intervention strategies.

One of the challenges inherent in working with individuals with ASD is that they display a very wide range of cognitive ability levels ranging from intellectual disability to intellectual giftedness. Diagnostic conventions have changed considerably over the last 20 years, and while it once was believed that 75% of affected individuals displayed intellectual disability, this figure now has dropped to about 40% according to a Centers for Disease Control publication in 2009 (Rice 2009). Twenty years ago, the most common finding was that individuals with ASD had an IQ profile with stronger visuospatial abilities (as assessed by the block design subtest) than verbal (and especially comprehension subtest) abilities (Goldstein et al. 2008). More recently, it has been argued that those with Asperger syndrome display the opposite profile ($VIQ > PIQ$) or that the intellectual profiles of those with ASD are no different than those found in the general population. These discrepancies may in part be explained by variations in the ages of samples and how they were ascertained. Recently, it has been demonstrated that persons with autism and Asperger syndrome perform better on intelligence tests that assess their perceptual and especially visual reasoning abilities (Raven's Progressive Matrices) versus more language-based tests like the Wechsler scales (Dawson et al. 2007).

Attention in Autism

There is an extensive research literature suggesting that individuals with autism exhibit

atypical patterns of attending to their environment. They may be poor at allocating attention to relevant visual stimuli, and they are at times overly selective and focused in what they attend to. They can find it hard to disengage from what they are viewing. They may have problems switching or redirecting attention between divided streams of information (i.e., visual and auditory stimuli). They may not pay attention to novel stimuli the same way as typically developing persons. This unusual attention processing may affect their development and learning and produce pattern of early emerging but persistent socio-communicative deficits (Dawson et al. 1998).

There are several different conceptual models of attention that have been used to study autism. The first was developed by Mirsky et al. (1991). According to this model, which was derived using a factor analysis (mathematical grouping by common features) of commonly used tests, components of attention include encoding (to receive and interpret incoming information), focusing and executing (to focus and perform a task in the face of distraction), sustaining (to maintain attention over time), and shifting (to adaptively shift the focus of attention). One well-known study in this area found that persons with ASD only showed deficits in focusing and executing and shifting (Goldstein, Johnson, and Minshew 2001).

According to another prominent view (Posner et al. 1984), attention is thought to have three components, which each is subserved by different neural networks and their interactions. The first of these, alerting, involves becoming more sensitive to incoming information on either a tonic (steady state) or episodic (in response to an event) basis. This network selects information from sensory input. The second component in this model is orienting. It is similar to attention shifting (see Allen and Courchesne 2001). The third component of attention is executive control, which is a multidimensional system responsible for inhibition, planning, conflict monitoring, and cognitive flexibility. Similar to Goldstein, Johnson, and Minshew (2001), a recent study using the Posner model found that orienting was impaired in individuals with ASD (Keehn et al. 2010).

Learning and Memory in Autism

Memory in autism is characterized by several unique features (see Boucher and Bowler 2008 for a recent volume on memory in autism). Individuals with cognitive ability levels in at least the average range tend to be as good as typically developing individuals on short-term memory tasks, including those involving auditory, visual, and motor stimuli. Across all functioning levels, they also demonstrate largely preserved non-declarative (implicit) memory (memory that occurs largely outside of conscious awareness). They also are unimpaired at memory tasks involving simple cued recall, where cues are provided to them. However, they are inefficient at spontaneously using contextual cues to help them remember and do not naturally use memory strategies that would leverage these cues. For example, they do not reliably employ grouping cues when presented with list learning tasks that contain semantically similar clusters of words that facilitate recall. Sometimes this failure to use presented cues can be an advantage. For example, they may produce fewer “false” memories on tasks that try to trick the participant into remembering nonpresented materials that are semantically similar to presented ones because they are not distracted by such lures. They also appear to lack the facilitated memory for materials related to themselves (self-referenced memory), which is present in typically developing individuals. They also show deficits in memory for information about emotions.

Individuals with ASDs also display a curious pattern of learning strengths and challenges. Their lower level learning involving contingency-shaped procedures, implicit information, single items of information/facts, and habits is intact. The effectiveness of interventions premised on operant conditioning such as applied behavior analysis (ABA), the ability to memorize large bodies of facts about special interests, and the preference for routines and sameness all constitute evidence of their bias toward lower level learning.

However, individuals with ASDs show deficits in higher level learning that relies on abstract goals and reasoning and on the efficient transfer of learning to new situations and problems

(known as generalization). In order to generalize, organisms must make and keep in mind relational links between memory traces that share common elements. This permits the transfer of what has been learned to novel contexts with similar but largely different features. Individuals with ASDs are inefficient learners. They exhibit excessively narrow stimulus discrimination at the expense of generalization (O’Riordan and Plaisted 2001). They often focus on idiosyncratic and overly selective aspects of stimuli. They fail to recognize and/or maintain online important cues signaling similarities across every day events and settings. Consequently, they are unable to leverage what they already know to navigate new situations. These deficits likely underlie the characteristic academic, social, and adaptive functioning problems they face.

Reasoning and Problem Solving in Autism

Abstract reasoning is a form of higher cognition that requires the mental process of considering and manipulating information about events, objects, and concepts not in the immediate environment. Abstract reasoning is thought to involve both the ability to identify concepts (i.e., to recognize underlying category attributes so as to better understand them) and the ability to form concepts based on these discriminations. This latter function has been referred to as generativity.

Concept identification abilities come online during the first year of life in typical development, and children with autism appear to acquire simple classification abilities involving the physical world (e.g., the ability to sort objects) similarly to children with other developmental delays. However, it is unclear whether individuals with autism can categorize based on more representational and abstract criteria. Some have found that lower functioning children have difficulty with sorting tasks that involve abstract categories, though older higher functioning individuals do not appear to have these difficulties.

In contrast to concept identification, concept formation involves an “open-field” situation in which the individual must initiate behaviors to solve a problem. This type of initiation, or

“generativity,” is recognized as a deficit area for children (Bishop and Norbury 2005) and adults (Turner 1999) with HFASD. Concept formation, but not concept identification, as assessed by the Goldstein-Scheerer object sorting task, has been found to differentiate children with HFASD from others.

Deficits in concept formation may limit the ability of individuals with HFASD to generate cognitive schemas that promote the efficient organization of social and nonsocial information. Impairments in the ability to create organizing schemas for initiating new social behaviors and routines (i.e., meeting new people, entering different and unstructured social situations, and/or conducting reciprocal conversations) would greatly disrupt daily social functioning. Similarly, the inability to conceptualize, represent, and integrate multiple perspectives would produce deficits in interpersonal relationships. The replicated finding that generativity is predictive of play quality in young children supports these assertions.

Several studies have used tasks similar to the guessing game “20 questions,” where players must guess the identity of items (persons, places, or things) in less than 20 questions. To perform well, they must ask efficient questions that narrow the possible guesses on each try. Individuals with ASD perform poorly on this task, and their task performance reliably distinguishes them from typically developing individuals. On this type of task, they tend to use strategies that eliminate single items versus groups of items. It has been suggested that this reflects a fundamental problem in concept formation – the spontaneous generation of categories to support goal-directed cognitive processing. These problems appear to be related somewhat to the executive function deficits of affected individuals.

Finally, following the study described above that high-functioning persons with autism perform better on the intelligence tests that involve more visuospatial versus verbal reasoning – the Raven’s Progressive Matrices test (Dawson et al. 2007) – there now have been several that show that aspects of conditional and analogical reasoning are relatively preserved in persons with ASDs.

Future Directions

Cognition is a very important topic in ASD research because it appears that the disorders involve unique strengths and challenges in this area, which are integrally related to educational, social, and behavioral functioning. A better understanding of cognitive style in ASD would produce important information that helps us understand the biological basis of the disorders and what to do to help those with them to achieve their human potential.

Some interesting areas for future research include:

1. More extensive use of evoked response potential studies which are particularly well suited to studying attention. These can be coupled with imaging studies to learn more about the neural substrates of higher cognition problems and what to do to help those with them.
2. The Raven’s Progressive Matrices findings outlined above are intriguing and point to the clear strengths of persons with ASD. We need more research to better elaborate such strengths and how they can be harnessed in the service of educational strategy development and vocational training.
3. The study of development of cognition through the lifespan in persons with ASD is in its infancy. The field is only now publishing findings about cognitive control in older adulthood. More studies are needed that cover the full range of cognitive abilities in toddlers, children, adolescents and adults with ASD.
4. There have been virtually no studies of decision making in persons with ASD. This is an important gap in knowledge, given that such these would be useful to help with the transition to adulthood.
5. More learning studies are needed to examine the neural substrates of learning in persons with ASD. These will help provide an evidence base for ABA and may teach us about effective strategies for helping persons with ASD to overcome their deficits in generalization.

Department of Pediatrics, Division of Pediatric Endocrinology, S. Demirel University, Isparta, Turkey

Definition

Cohen syndrome (Mendelian Inheritance in Man [MIM 216550]) is an autosomal recessive disorder which was first described in 1973 by Cohen and coworkers (Cohen et al. 1973). The first patients studied with Cohen syndrome were reported to have mental retardation, microcephaly, antimongoloid slant, mild maxillary hypoplasia, short philtrum, open mouth with prominent maxillary central incisors, micrognathia, highly arched narrow palate, crowded teeth, hypotonia, obesity, narrow hands and feet, tapering extremities, cubitus valgus, genua valga, lumbar lordosis, mild thoracic scoliosis, and hyperextensibility of the joints. Subsequent to this first report, there have been descriptions in the literature of more than 100 patients suggested to have Cohen syndrome Fig. 1.

Historical Background

History

In 1968 and 1972, Dr. Michael Cohen and his collaborators from the United States observed

Cohen Syndrome, Fig. 1 Case 1 showing the characteristic facial appearance (a). Case 2 showing the characteristic body shape of Cohen syndrome: a truncal distribution of body fat, with comparatively slender limbs (b). Case

3 showing the prominent upper incisors, high nasal bridge, and antimongoloid slant of the eyes (c) (From archive of Ozgur Pirgon)

two sibs and a third patient, respectively, with a previously unrecognized pattern of abnormalities. In 1973, they diagnosed these patients with a newly recognized syndrome (Cohen et al. 1973). In another report, Carey and Hall established Cohen syndrome as a clinical entity by presenting four new patients with similar findings (Carey and Hall 1978).

Since then, a large number of patients with Cohen syndrome have been found in Finland. Six of these were reported in 1984 by Norio et al. on a small group of Finnish patients with Cohen syndrome, presenting microcephaly, neutropenia, and specific ophthalmic abnormalities, namely, high myopia and retinal dystrophy (Norio et al. 1984). Recently, a novel disease-causing gene (COH1; chromosome 8q22) was identified in this interval which encodes a transmembrane protein presumably involved in vesicle-mediated sorting and intracellular protein transport (Kolehmainen et al. 2003).

Genetics and Etiology

Many of the reported patients have been sibs, with healthy parents. In five Finnish families, the parents were consanguineous. Thus, Cohen syndrome is considered to be an autosomal recessive disorder. In Finland, linkage studies were performed with the assumption of autosomal recessive inheritance, and the gene was mapped to

the long arm of chromosome 8 (Tahvanainen et al. 1994).

The gene responsible for Cohen syndrome, VPS13B (MIM# 607817), also known as COH1, is located on chromosome 8q22 (Kolehmainen et al. 2003). VPS13B is a large gene: it spans a region of 864 kb and has 62 exons, with putative transmembrane domains and functional motifs specific for intracellular vesicle-mediated protein sorting (VPS) (Kolehmainen et al. 2003; Seifert et al. 2009; Velayos-Baeza et al. 2004). The function of the protein encoded by COH1 is mostly unknown. Although in the majority of patients clinically diagnosed as having Cohen syndrome, homozygous or compound heterozygous mutations in VPS13B are identified, in about 20–30%, only one heterozygous mutation is detected, and in 12%, no mutations are found (Kolehmainen et al. 2004; Seifert et al. 2009). Overall, more than 50 COH1 mutations have been reported in association with Cohen syndrome. Most are termination mutations and predicted to result in a null allele, while missense mutations and larger deletions are less common (Seifert et al. 2006). For these patients, the underlying cause remains uncertain.

The mouse homologue of COH1 is widely expressed in neurons of the postnatal and adult brain suggesting a role in neuronal differentiation (Mochida et al. 2004). This suggests that COH1

primarily functions in postmitotic cells, which may be the reason for the postnatal microcephaly seen in Cohen syndrome (Seifert et al. 2006).

Incidence and Prevalence

Cohen syndrome is a rare autosomal recessive disorder with incidence rates (based on Finnish data) estimated as 1 per 105,000 (Kivitie-Kallio et al. 1999). To date over 100 reports of individuals with Cohen Syndrome have been published, but most are single case or small group studies, and relatively few involve large samples. Patients have been identified worldwide but are overrepresented in the Finnish population.

Diagnosis

Establishing the clinical diagnosis of Cohen syndrome has historically been challenging. The first patients studied with Cohen syndrome were reported to have mental retardation, microcephaly, antimongoloid slant, mild maxillary hypoplasia, short philtrum, open mouth with prominent maxillary central incisors, micrognathia, highly arched narrow palate, crowded teeth, hypotonia, obesity, narrow hands and feet, tapering extremities, cubitus valgus, genua valga, lumbar lordosis, mild thoracic scoliosis, and hyperextensibility of the joints.

The clinical diagnosis of Cohen syndrome is difficult to make in infancy. At infancy, the characteristic facial features are difficult to recognize, but they become more and more evident by 5–10 years of age and remain recognizable for decades but tend to lose their most characteristic appearance after middle age (Kivitie-Kallio et al. 2001). Neonatal feeding problems are common. Babies are often hypotonic during the first months of life.

The initial description of Cohen syndrome features included obesity, mental retardation, hypotonia, narrow hands and feet, and a distinctive craniofacial appearance (Cohen et al. 1973). Broad phenotypic variability in subsequent patients diagnosed with Cohen syndrome has created significant confusion as to diagnostic accuracy (Chandler and Clayton-Smith 2002; Friedman and Sack 1982). The characteristic facial appearance, developmental delay, myopia,

narrow hands with slender and tapering fingers, narrow feet, and generalized joint hyperextensibility were present in all patients with Cohen syndrome investigated for their study. However, microcephaly, short stature, truncal obesity, neutropenia, and retinopathy were not present in some of the patients.

Greater clinical variability is observed in case reports of Cohen syndrome from outside Finland. A comparison of features among different Cohen syndrome populations with shared linkage to the COH1 locus or known COH1 gene mutations may help better define criteria for which to suspect Cohen syndrome.

Although the various physical abnormalities associated with Cohen syndrome have been widely documented, there is still a lack of consistency in diagnosis. The facial features are often a first indication of a diagnostic pathway in the examination of patients presenting with developmental delay.

In 2001, Kivitie-Kallio and Norio proposed the following features as essential for the diagnosis of Cohen syndrome:

1. Nonprogressive mental retardation, motor clumsiness, and microcephaly
2. Typical facial features, including wave-shaped eyelids, short philtrum, thick hair, and low hairline
3. Childhood hypotonia and joint hyperextensibility
4. Retinochoroidal dystrophy and myopia by 5 years of age
5. Periods of isolated neutropenia

In 2003, Chandler et al. linked the diagnosis of Cohen syndrome to the presence of at least two of the following major criteria in a child with significant learning difficulties:

1. Facial gestalt, characterized by thick hair, eyebrows, and eyelashes; wave-shaped, downward slanting palpebral fissures; prominent, beak-shaped nose; short, upturned philtrum with grimacing expression on smiling
2. Pigmentary retinopathy
3. Neutropenia (defined as $<2 \times 10^9/L$)

Cohen Syndrome, Table 1 Diagnostic criteria for diagnosis of Cohen syndrome seen in individuals from various ethnic backgrounds with proven COH1 mutations (Falk et al. 2004)

<i>Major signs</i>	Retinal dystrophy appearing by midchildhood
	Progressive high myopia
	Acquired microcephaly
	Nonprogressive mental retardation, global developmental delay
	Hypotonia
	Joint hyperextensibility
<i>Minor signs</i>	Truncal obesity appearing in or after midchildhood
	Small or narrow hands and feet
	Short stature
	Friendly disposition
	Noncyclic granulocytopenia or low total white blood cell count with or without aphthous ulcers

In association with a number of less specific but supportive criteria, namely:

- 1. Early-onset, progressive myopia
- 2. Microcephaly
- 3. Truncal obesity with slender extremities
- 4. Joint hyperextensibility

See (Table 1)

Current Knowledge

Differential Diagnosis

Conditions to be considered in the differential diagnosis of the Cohen syndrome include the Prader-Willi syndrome, Rubinstein-Taybi syndrome, Borjeson-Forssman-Lehmann syndrome, Bardet-Biedl syndrome, and Mirhosseini-Holmes-Walton syndrome. Mirhosseini-Holmes-Walton syndrome may be the same syndrome as Cohen syndrome (Steinlein et al. 1991). However, the clinical phenotype of these conditions is quite distinct and very different from that of Cohen syndrome. Deafness, diabetes mellitus, and cardiomyopathy are characteristic of Alström syndrome while the patients are usually of normal intellect (Michaud et al. 1996). Postaxial

polydactyly and renal dysplasia are diagnostic features of Bardet-Biedl syndrome (Beales et al. 1997). Prader-Willi syndrome is characterized by severe hypotonia and feeding difficulties in early infancy, followed in later infancy or early childhood by excessive eating and obesity.

Specific Characteristics

Cohen syndrome has been proposed to be subdivided into two types (i.e., Finnish type and Jewish type) (Kondo et al. 1990). Phenotypes common to both types are nonprogressive psychomotor retardation, microcephaly, characteristic facial features, retinal dystrophy, and intermittent neutropenia (Friedman and Sack 1982; Sack and Friedman 1986). The characteristic facial features include high-arched or wave-shaped eyelids, a short philtrum, thick hair, and low hairline. Both types are further classified by the presence (Finnish type) or absence (Jewish type) of retinal anomalies (Kondo et al. 1990).

Neurological

Intracranial abnormalities have been reported in Cohen syndrome patients; however, the findings are inconsistent. Microcephaly, considered by some authors (Fryns et al. 1996; Norio et al. 1984) as a typical and early symptom of the syndrome, was mildly evident from the neonatal period in our two patients and, apart from mild hypotonia, was not associated with major neurological dysfunction (Balestrazzi et al. 1980; Carey and Hall 1978).

Hypotonia can be either of central origin or related to a possible connective tissue disorder (Norio et al. 1984). All patients learn to walk by the age of 2 ± 5 years. The incidence of seizures in Cohen syndrome is approximately 6% (North et al. 1985). EEG abnormalities in Cohen syndrome have also been reported in two cases by Goecke, Majewski, Kauther, and Sterzel (1982). Except for oppiness, no signs of muscle disease are found.

Brain MRI is considered normal, although corpus callosum is relatively enlarged. Previous studies on MRI findings in Cohen patients disclosed no focal signal intensity alterations in the brain and no alterations between the gray and white

matter (Kivitie-Kallio et al. 2001). Furthermore, some authors reported in some patients with Cohen syndrome a relatively enlarged corpus callosum, thus suggesting to consider this a possible hallmark of the syndrome. An increased diameter of the body of the corpus callosum was described in a group of 15 Finnish Cohen syndrome patients (Kivitie-Kallio and Norio 2001), a clinical feature not reported by other large studies of non-Finnish Cohen syndrome patients (Hennies et al. 2004; Kolehmainen et al. 2004; Seifert et al. 2006).

All authors also proposed that though MRI alone cannot confirm the diagnosis and no definite measurements can be recommended for clinical use, any clinical suspicion of Cohen syndrome would have been reinforced by the MRI finding of an enlarged corpus callosum in a microcephalic head and normal signal intensities of gray and white matter (Kivitie-Kallio et al. 2001).

Craniofacial

Craniofacial features are often essential in syndrome diagnosis. Suspicion of Cohen syndrome usually arises when a mentally retarded child has facial features considered typical of this syndrome. Reduced head size (microcephaly), short philtrum, and small cranial base dimensions are essential features in Cohen syndrome. In addition, most patients had forward-inclined upper incisors and maxillary prognathia (Carey and Hall 1978; Ozturk and Weber 1991). Head circumferences of Cohen subjects were very small, in the order of mean values for 5–6-year-old Finnish children and at the level of -4 SD in Finnish head circumference standards (Sorva et al. 1984).

Other craniofacial features, such as anti-mongoloid slant of the eyelids, high-arched or wave-shaped eyelids, long and thick eyebrows, prominent root of nose, short philtrum, prominent upper central incisors, open mouth appearance, maxillary hypoplasia, high and narrow palate, and mandibular micrognathia, have been described (Goecke et al. 1982; Kondo et al. 1990; Warburg et al. 1990).

Despite variability in the facial appearance, several specific features can be identified in patients from different countries. Facial features

also seem to differ between populations. Finnish Cohen syndrome patients (81–100%) are described as having a distinctive facial appearance including wave-shaped eyelids, thick and high-arched eyebrows, long eyelashes, thick hair, low hairline, high nasal bridge, flat philtrum, short upper lip, prominent and broad upper central incisors, open mouth, and micrognathia (Kivitie-Kallio and Norio 2001). The UK cohort was found to have a similar facial appearance as the Finnish, with the additional description of a beak-shaped nose, malar hypoplasia, and a grimace-like smile (Chandler et al. 2003).

Ophthalmologic

Cohen syndrome is also characterized by progressive myopia and pigmentary retinopathy, as first described in two of three patients by Cohen et al. (1973). Other reported ophthalmic features include astigmatism, strabismus, microcornea, microphthalmia, sluggish pupillary reaction, iris atrophy and oval pupil, lens opacities, lens subluxation, optic atrophy, bull's-eye maculopathy, coloboma of the retina or lids, ptosis, exophthalmos, poor vision acuity, nyctalopia, and constricted visual fields (Chandler and Clayton-Smith 2002; Kivitie-Kallio et al. 2000). In the UK study, however, a significant proportion of affected adults were found to develop blindness with time (Chandler et al. 2002).

Retinal dystrophy was recorded by Cohen et al. (1973) in their original description of the syndrome. The pigment deposits increase and approach the posterior pole by 35–40 years of age (Kivitie-Kallio et al. 2000). All except two children aged 2 and 5 years of the 22 Finnish patients showed signs of the pigmentary retinopathy (Kivitie-Kallio et al., 2000). Early studies of Cohen syndrome patients showed that abnormal retinal findings and electroretinographic changes were present much earlier (Chandler et al. 2002). Useful vision is usually preserved until the fourth decade (Kivitie-Kallio et al. 2000).

Retinal dystrophic changes were accompanied by early night blindness. This symptom is commonly seen in adolescents. In Cohen syndrome; ocular anomalies are also common finding

including strabismus, hyperopia, astigmatism, microphthalmia, coloboma of the iris, and, most frequently, severe myopia. Recent reports also indicate involvement of the chorioretinal epithelium (Mendez et al. 1985; Norio et al., 1984).

Myopia and astigmatism are common findings in Cohen syndrome. Myopia was noted in 44% of patients in the literature. Myopia in Cohen syndrome is mainly refractive in type and is due to high corneal and lenticular power (Summanen et al., 2002).

Strabismus was reported in 29% of patients from literature review, with divergent strabismus being more common than convergent (Fryns et al., 1996; Warburg et al., 1990). Chandler et al. (2002) reported strabismus in up to 80% of patients. Downslanting eyelids were present in 71% of patients, while 13% were reported to have ptosis. Lens opacities were present in 13 of 22 Finnish patients (Kivitie-Kallio et al., 2000). Small cortical opacities were noted in patients as early as 15 years of age; biomicroscopy and lens opacitometry show frequent incidence of early nuclear sclerosis in patients with Cohen syndrome (Summanen et al., 2002). Older patients also had posterior subcapsular cataracts, iris atrophy, and iridophacodonesis (Kivitie-Kallio et al., 2000).

Musculoskeletal

In the first report of this syndrome, all of the three patients had lumbar lordosis, mild thoracic scoliosis, cubitus valgus, genu valgum, and narrow hands and feet (Cohen et al., 1973). The hands and fingers of Cohen patients were reported to be long and slender (Kousseff, 1981; Norio et al., 1984). Since the first descriptions, the most common abnormalities reported are kyphoscoliosis and pes calcaneovalgus (Norio et al., 1984; North et al. 1985; Sack and Friedman 1986).

The metacarpophalangeal pattern profile was characteristic: all measured bones of the hands were short, the medial and especially the distal phalanges were the shortest, and the proximal phalanges were relatively the longest. Their hands and feet are small and narrow, as given in earlier reports (Cohen et al. 1973; Norio et al. 1984).

Endocrine

In many previous studies, Cohen syndrome patients have been reported to be short (Carey and Hall 1978; Cohen et al. 1973; North et al. 1995). Short stature is a universal feature among the Amish and Lebanese Cohen syndrome patients, but was seen in only 40% of the Finnish Cohen syndrome patients and 64% of the UK Cohen syndrome patients. Heights were highly variable and ranged from -5.7 to -0.3 SD. Both impaired growth hormone (Massa et al. 1991) and normal growth hormone secretion have been reported (Carey and Hall 1978).

Mild truncal obesity was present in most patients at midchildhood, but that trait may be lacking in adult patients. Other studies have described different frequencies of truncal obesity, from 17% to 100% in patients aged ≥ 8 years (Chandler et al. 2003; Kivitie-Kallio and Norio 2001).

Puberty in Cohen syndrome patients is mostly delayed (Kivitie-Kallio et al. 1999), although they do reach sexual maturity. Delayed puberty has only been reported in the Finnish and UK cohorts (77% and 40%, respectively). No endocrine abnormalities are found. The other reported endocrinologic study showed delayed onset of puberty without luteinizing hormone and follicle-stimulating hormone deficiency in Cohen syndrome (Balestrazzi et al. 1980). However, delayed puberty might be due to the obesity.

Two girls, one with diabetes mellitus (Nambu et al. 1988) and the other with impaired glucose tolerance test (Fuhrmann-Rieger et al. 1984), have been noted. No abnormalities of the hypophyseal-gonadal axis were found. Kivitie-Kallio et al. found no significant endocrinologic abnormalities in their patients with Cohen syndrome; however, they did not perform an oral glucose tolerance test in their obese cases for diabetes or insulin resistance (Kivitie-Kallio et al. 1991).

Pirgon et al. reported that two patients showed the typical characteristics of Cohen syndrome with metabolic syndrome features of acanthosis nigricans, hyperlipidemia, hypertension, and marked hyperinsulinemia (Pirgon et al. 2006).

Developmental Delay and Mental Retardation

All patients had a global developmental delay of variable degree and nonprogressive mental retardation. Intellectual impairment is considered to be an essential criterion by some groups of researchers (Kivitie-Kallio and Norio 2001).

Mental retardation together with motor delay, due to hypotonia, is present from early life in most reported cases of Cohen syndrome. The majority of patients have an IQ less than 50 (Goecke et al. 1982), although there have been reports of children showing mild to moderate degree of retardation. Most reported cases of Cohen syndrome present with mental retardation accompanied by motor delay and hypotonia in early life. Patients are not able to attend normal school; thus, they all need special schools. Mental retardation does not progress, and patients learn new things.

Behavioral

Cohen syndrome patients usually have cheerful disposition and have not been associated with maladaptive behavior. Language is possibly lacking or severely impaired in infancy. Autistic traits are found during childhood (Fryns et al. 1996). Children and young people diagnosed with Asperger's syndrome have significant social-communication difficulties and impaired empathy and theory of mind skills. These difficulties place them at risk of developing mental health problems, particularly anxiety, depression, and obsessive-compulsive disorder.

A recent study of cognitive and adaptive skills (Karpf et al. 2004) indicated that some individuals may have an IQ in the normal range, and although some research (Kivitie-Kallio et al. 1999) has reported low levels of maladaptive behavior and high levels of self-direction, responsibility, and socialization, there are also accounts of greater behavioral disturbance (Chandler et al. 2003). Fryns et al. (1996) reported autistic behavior patterns in four patients and in a postal survey of 33 children and young adults with Cohen syndrome.

Reports from a number of parents belonging to the Cohen Syndrome Support Group in the UK had indicated significant difficulties in social interaction; moreover, there were several cases

of individuals with Cohen syndrome also being diagnosed as having autism. Howlin (2001) found that over half the sample had problems in social understanding, communication, and ritualistic and stereotyped behaviors. Howlin et al. (2001) also suggested that although antisocial behaviors are rare, symptoms of anxiety are common, and in some individuals, autistic-type features are marked. Their investigation of 45 individuals with Cohen syndrome (age 4–48 years) found that although 57% of the sample were reported as showing some behavioral disturbance, problems related mainly to anxiety and social interactions, marked antisocial behaviors were rare.

Kivitie-Kallio and her colleagues (Kivitie-Kallio and Norio 2001) noted that “inappropriate interpersonal manners, stereotyped behavior and odd mannerisms were not uncommon.” One of their cases had also shown autistic behavior as an infant, although this had improved after the age of 3 years. In the Chandler et al. study (2003) of 27 patients, 74% exhibited stereotyped behaviors, such as spinning, and five cases (18%) were observed to show autistic features (communication and social abnormalities and ritualistic and obsessive behavior).

Infections

Many children with Cohen syndrome have recurrent upper respiratory infections. However, patients have no fatal infections, and granulocytes seem to rise normally in cases of severe bacterial infections.

Several of the children had intermittent granulocytopenia. The granulocytopenia is usually mild, not progressive, and does not seem to be associated with recurrent infections. While intermittent granulocytopenia is frequently described in the Finnish group (100%), UK group (77%), and was present in two Amish patients evaluated for this problem with one additional child having symptomatic aphthous ulcers, it was not present in blood counts of any of the Lebanese Cohen syndrome patients. Importantly, no severe infections were reported in association with this finding.

Chandler et al. (2003) reported that stridor secondary to laryngomalacia was common in

infancy among the Jewish-type Cohen syndrome patients and more significant laryngeal abnormalities were also reported, namely, laryngeal stenosis and vocal cord paralysis.

Cardiovascular

Numerous cardiac abnormalities have been reported. These include mitral valve prolapse in two patients (Sack and Friedman 1980; Mehes et al. 1988). Systolic murmur (grades II–IV) in five of six patients (Norio et al. 1984) and a dilated descending aorta (Schlichtemeier et al. 1994) have also been reported. Although 30% of the patients had systolic murmurs, echo studies revealed no abnormalities in their cardiac anatomy.

Future Directions

Management

Early diagnosis of the syndrome is important for appropriate counseling of families with one affected child. Although most of the clinical findings are usually present from an early age, the diagnosis of Cohen syndrome is very difficult in infancy, since the typical morphological stigmata become more evident after the age of 6–8 years (Fryns et al. 1996).

Newborns have low-normal weights, and the onset of obesity is generally in midchildhood (Carey and Hall 1978; Cohen et al. 1973). Severe obesity is rare, and some patients may not develop obesity at all (Friedman and Sack 1982). The relationship among the obesity, hypotonia, and hypogonadism has not been clarified. Nutritional counseling for good long-term weight management should begin in early infancy to prevent the inappropriate weight gain that would otherwise typically begin between 12 and 36 months of age.

Behavioral problems should be detected early and treated appropriately with parental education/training (including consistent limit setting) and, if needed, consideration of counseling and/or psychotropic medication. Developmental assessment should be performed routinely. Physical and occupational therapies should begin in infancy to facilitate the development of motor milestones.

Speech therapy is important in monitoring receptive-expressive language skills. In addition, appropriate educational intervention throughout the school years that addresses individual strengths and challenges as well as behavioral issues can be effectively implemented in both inclusion and self-contained classroom settings depending on individual needs.

Long-term follow-up and clinical information on patients older than 40 years are rare in the literature. Marked deterioration of visual function, and even total blindness, can occur over the age of 50 years (Seifert et al. 2006). Kyphoscoliosis can be observed in patients with Cohen syndrome as teenagers or adults, and this tends to be progressive through adult life.

Appropriate management of children with Cohen syndrome requires collaborative efforts from the geneticist, neurologist, endocrinologist, developmental-behavioral pediatrician, nutritionist, psychologist, psychiatrist, educational specialist, and the family. Once the diagnosis of Cohen syndrome is confirmed, it is important for the child to receive multidisciplinary care in addition to routine preventive health care from the primary care physician.

Cohen, Donald J.

Andres Martin

Yale Child Study Center, New Haven, CT, USA

Name and Degrees

Donald J. Cohen, M.D. (1940–2001).

Major Appointments (Institution, Location, Dates)

- Director, Yale Child Study Center, 1983–2001.
- President, International Association of Child and Adolescent Psychiatry and Allied Professions, 1992–1998.

Major Honors and Awards

- Doctorate Honoris Causa, Bar-Ilan University, 1997.
- Lifetime Achievement Award, International Meeting for Autism Research, 2001.

Landmark Clinical, Scientific, and Professional Contributions

Donald Cohen was the leading American child psychiatrist of his generation and helped advance the neurobiological study of autism, initially through his work in the 1970s and 1980s on serotonin and monoamines in cerebrospinal fluid and later by developing cross-disciplinary research collaborations at the Yale Child Study Center and beyond. Under his directorship, the research program on autism at Yale broke new ground, among other areas, in nosology (through the DSM field trials led by Fred Volkmar), phenotypic definition (through Ami Klin's eye tracking paradigms), and neural substrates (through Robert Schultz's imaging studies of the fusiform gyrus). In addition, Cohen brought to autism research his background in philosophy and psychoanalysis, as exemplified

in his collaborations on theory of mind with Simon Baron-Cohen, and on the contributions of psychoanalysis to social development with Linda Mayes.

Short Biography

Born in Chicago in 1940 to a humble family, Donald Cohen attended college at Brandeis University. He studied philosophy at Cambridge before enrolling in medical school at Yale. He trained in pediatrics at Children's Hospital Boston and in psychiatry at the Massachusetts Mental Health Center. During his time in Boston, he worked with Ogden Lindsay in his operant conditioning laboratory. During the Vietnam War, he worked in Washington, D.C., as special assistant to Edward Zigler, helping him in the development of the Head Start program. Cohen was recruited back to Yale in 1972 by Albert Solnit, whom he succeeded as director of the Yale Child Study Center in 1983. At Yale, Cohen was able to integrate his background in philosophy, psychoanalysis, and neuroscience particularly on two "model" disorders: Tourette's syndrome and autism. His early studies on monoamine metabolites in serum and CSF were conducted at the Children's Clinical Research Center (CCRC) at Yale-New Haven Children's Hospital. Cohen was codirector of the CCRC from the time of his arrival at Yale until his succession by his close collaborator James Leckman in 1983. Cohen's early studies on monoamine metabolites were followed by his development of a rich multidisciplinary research program for autism at the Yale Child Study Center. Key collaborators in this program were Fred Volkmar (who eventually would go on to lead it), Ami Klin, Robert Schultz, Rhea Paul, and George Anderson. In addition to a wide portfolio on neurobiological studies of autism, Cohen remained interested and made seminal contributions to theory of mind and the inner life of individuals with autism, as well as to the ethical imperative to conduct sound research in

vulnerable populations, including individuals affected with autism. Much of Cohen's later career was devoted to establishing international programs in child and adolescent psychiatry, a focus that he developed as president of the International Association of Child and Adolescent Psychiatry and Allied Professions.

Collaborative Program of Excellence in Autism

Alice Kau¹ and Judith Cooper²

¹Intellectual and Developmental Disabilities (IDD) Branch, Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, MD, USA

²NIDCD (National Institute on Deafness and Other Communication Disorders), National Institute of Health EPS – Executive Plaza South, Rockville, MD, USA

Major Areas or Mission Statement

The mission of the CPEA network was to increase empirical knowledge about autism through the use of (1) multiple levels of interdisciplinary investigation into the genetics, neurobiology, and clinical aspects of autism; (2) rigorous phenotyping of research participants to support network-wide studies of large numbers of participants; and (3) a collaborative process of sharing data, findings, and ideas to move the science ahead as quickly as possible. The purpose of this network was to gain knowledge that could lead to prevention, treatment, and/or amelioration of the disabling effects of autism on people with autism and their families.

Landmark Contributions

The CPEA network was created as result of a congressionally mandated conference on the State of the Science in Autism, which took place in April 1995, to identify gaps in the knowledge of autism and directions for future research. The NICHD and the NIDCD joined together in 1997 to fund a 5-year project that consisted of nine clinical centers that each had a unique focus of autism research. The CPEA network was funded through an NIH Cooperative Agreement mechanism. Funding was secured in 2002 for a second

5-year cycle. The primary goal of this program was to bring together expertise, infrastructure, and resources focused on major questions about autism. The research issues addressed include advanced techniques of diagnosis and assessment, population genetics and molecular biology, structural and functional brain imaging, animal models, behavioral and cognitive neuroscience, and focused interventions, to elucidate the neurobiology of autism, with the long-term goal of effective diagnosis, treatment, and prevention. The CPEAs have linked scientists from the United States, Canada, Britain, and five other countries in the study of more than 2,200 families over 10 years. As a result, the CPEAs have data on the genetic and phenotypic characteristics of the world's largest group of well-diagnosed persons with autism. The funding of the network ended in 2007 when the NIH consolidated its funding for autism research into other programs.

Major Activities

The CPEA network conducted basic and clinical research on the possible genetic, immunological, neurobiological, and environmental causes of autism. The network also investigated the developmental course of autism and how specific brain structures were related to autism. These undertakings required that each CPEA implement a cohesive, site-specific, multidisciplinary research program on the causes, brain substrates, functional characteristics, and clinical development of autism. In addition, each site participated in a trans-network collaborative study for which no single site had sufficient expertise and/or participant sample size. Network projects evaluated the effectiveness of the hormone, secretin, in the treatment of autism (Owley et al. 2001; Unis et al. 2002); the candidate autism genes, *HOXA* and *Reelin* (Devlin et al. 2002, 2004); the onset of regression and measles-mumps-rubella vaccination (Richler et al. 2006); early regression in social communication in autism (Richler et al. 2006); the heterogeneous association between *Engrailed-2* and autism (Brune et al. 2008); familial autoimmune thyroid disease and regression in autism

(Molloy et al. 2006); frontal lobe function in people with autism (Ozonoff et al. 2004); the relationship between head circumference and autism (Lainhart et al. 2006); and IQ-based subtypes of autism (Munson et al. 2008).

Collateral Effects of Youth Disruptive Behavior Disorders on Mothers' Psychological Distress: Intellectual Disability, or Typical Development

Bruce L. Baker¹ and Jan Blacher²

¹Department of Psychology, University of California Los Angeles, Los Angeles, CA, USA

²Graduate School of Education, University of California, Riverside, Riverside, CA, USA

Definition

Our focus herein is on how disruptive behavior disorders in youth with intellectual disability and/or autism spectrum disorder impact their families. We further examine the mitigating effects of positive beliefs and dispositional optimism on parents' distress.

Historical Background

Impact of Child Developmental Disability on the Family

It has long been recognized that raising a child with a developmental disability, such as autism, impacts families. These impacts are usually framed as parenting challenges, though more recent researchers have noted positive impacts as well. While some disabilities are apparent at birth (e.g., Down syndrome), others become apparent as the child develops (e.g., mild delays, autism). Thus, four facets of developmental risk and families become obvious: The first is that the impact on families relates to the nature of the child's disorder. The second is that this impact is also related in some ways to the family's strengths and resources. The third is the extent of effective support services that are available to the family. A fourth, which we focus on in this article, is when the developmental disability is compounded by behavior problems and/or mental disorders, which are more likely in children and youth with developmental disabilities. Relatedly, these disorders themselves, especially when compounded by concomitant psychological problems, have collateral effects on parents.

The literature reviewed here speaks to youth with autism spectrum disorder as well as to those with intellectual disabilities, together considered developmental disorders. To a more limited extent, it speaks to impacts on fathers as well as mothers. This section briefly reviews the impacts on families of the child's disability itself, within a historical perspective. The next section addresses in more detail the collateral effects on families when the developmental delay is comorbid with behavior problems and/or mental disorders. The final section provides examples of protective factors for parent and family adjustment, with an illustrative focus on dispositional optimism.

Looking back: Historically, developmental disorders were not only viewed as tragedy, but also with a sense of hopelessness. Some writers spoke to devastating effects, as does the classic paper by Simon Olshansky (1962) who wrote of “chronic sorrow.” He proposed that the adjustment to a retarded child (the terminology of the era) is not

time-bound, but that over time repeated sadness, and even intense grieving, is periodically experienced. Indeed, the common advice of the times was to institutionalize the child, and state-run “training schools” across the USA had become lifelong residences for many.

Now almost six decades later: A number of developments have tempered the negative aspects of raising a child with a disability, in the views of professionals and the lived experience of parents. These changes in the USA, still progressing, have included (a) a marked decline in out-of-home care; (b) legislation mandating free and appropriate education for all handicapped children, codified in the 1975 Public Law 94–142 and more recently in 2004 as IDEA; (c) expanded early childhood programs; (d) considerably increased funding for related research and services; (e) innovations in evaluations and educational curricula; (f) more visibility of children and adults with disabilities in society; and (g) recent media attention to the marked increase in autism spectrum disorder (ASD). These, and other developments, along with more positive family perspectives, are accompanied by increasingly accepting societal views of persons with developmental disabilities.

While parents today certainly still experience the complex of emotions associated with raising a child with a developmental disability – and in many cases experience these sooner with earlier diagnoses – they also find wider community awareness and acceptance and earlier access to services. The developmental disability literature in the past two decades, while acknowledging the panoply of emotions and challenges parents still experience, is increasingly focused on gaining a better understanding of family needs and strengths.

Developmental disorders and effects on families: Over the past two decades, studies of families raising a child with a developmental disability have focused mainly on parenting stress and factors that reduce it. Patton et al. (2018), for example, studied carers for adolescents with ID vs. those with typical cognitive development (TD), finding that parents of youth with ID experienced significantly higher levels of stress.

Similarly, a meta-analysis analyzed parent-reported stress in families of children with autism spectrum disorder (ASD) vs. families with typically developing children (TD) (Hayes and Watson 2013). The authors found a large effect size indicating greater stress with ASD.

While emphases, understandably, have been on negative impacts of child disability on the family, and while perceived positive impacts do not negate these, it is important to report that many parents can readily find the “sunny side of the street” (Blacher et al. 2013a). Studies have examined positive impacts on the family of having a child with a disability and variables associated with positivity (e.g., Bayat 2007; Blacher and Baker 2007). One found that family resources, including higher income, time for interaction with the child, and social support, predicted lower parenting stress better than did aspects of the child’s functioning (Smith et al. 2001). Parents’ social support was also found to be a buffer, as carers with higher social support were no more stressed than carers for typically developing children. Parents’ well-being and positive relationships are also protective factors. Gerstein et al. (2009) examined parents’ resilience and the course of daily parenting stress across the preschool years for their child with intellectual disability (ID). Overall mothers’ daily parenting stress did increase some over time, while fathers’ stress remained more constant. For mothers with decreased stress, this was associated with both mother’s and father’s well-being and their perceived good marital adjustment, as well as a positive father-child relationship. Father’s stress trajectory was affected only by mothers’ well-being and both parents’ marital adjustment. A study of perceptions of positive impact examined 219 families annually from child ages 3 through 9, examining two predictors: child disability status (ID or TD) and family culture (Anglo, Latino) (Blacher et al. 2013b). Anglo mothers initially reported significantly lower positive impact when their child had an ID, but Latino mothers did not. Across all time points, Latino mothers reported higher positive impact than Anglo mothers, regardless of whether they had a child with ID or TD.

While parents today certainly still experience the complex of emotions associated with raising a child with a developmental disability — and in many cases experience these sooner with earlier diagnoses — they also find wider community awareness and acceptance and earlier access to services. The developmental disability literature in the past two decades, while acknowledging the panoply of emotions and challenges that parents still experience, is increasingly focused on gaining a better understanding of family needs and strengths. Studies are going beyond descriptions of family impacts, to examine child, parent, and family characteristics that promote acceptance and support.

Current Knowledge

Child Developmental Disability and Collateral Behavior Problems and/or Mental Disorder

Beyond the impact that children with disabilities have on their parents and families are two related observations: *First, youth with developmental disorders are significantly more likely than typically developing youth to have collateral behavior problems and/or diagnostically classified psychiatric disorders. Second, the combination of youth disabilities and diagnoses will have a heightened impact on their parents and family.* We will first examine the increased prevalence of behavior/mental disorders in youth with ID and ASD and then consider how children with both a developmental disability and also collateral behavior problems/mental disorder impact their families.

Heightened behavior/mental health disorders. Many studies, especially in the last two decades, have addressed comorbid behavioral and mental disorders. We will first focus on ASD. One study conducted a semi-structured interview with parents of school-aged children with ASD or control youth. There were significantly higher rates of ADHD, but also of anxiety disorder, in the youth with ASD (Rosa et al. 2016). This finding is consistent with many other studies (e.g., Leitner 2014; Simonoff et al. 2008). The true incidence may be even higher, as Leitner and colleagues (2014) pointed out that the widely used

Diagnostic and Statistical Manual (DSM-IV) had ASD diagnosis as an exclusion criterion for ADHD, thus limiting research on their common co-occurrence. This exclusion was eliminated in 2013, with the publication of DSM-V, so we might expect even greater comorbidity reported since then.

Focus on Autism: One frequent comorbidity is autism spectrum disorder (ASD) and the mental health diagnosis of attention deficit hyperactivity disorder (ADHD). This paired comorbidity has both high incidence and considerable impact on families. ADHD is defined by impaired functioning in the areas of attention, hyperactivity, and impulsivity, whereas ASD is characterized by core social communication deficits and restrictive-repetitive behaviors. Studies have shown that between 30 and 50% of children with ASD manifest ADHD symptoms (particularly at preschool age), and, similarly, estimates suggest two-thirds of individuals with ADHD show features of ASD (Davis and Kollins 2012).

Other studies of comorbid disorders in young children with ASD have found high rates of language problems, intellectual disability, below average motor function, and severe hyperactivity, ranging from 33% to 78% of this child group (Carlsson et al. 2013). In a major study from 14 sites in the USA and in Canada, Sikora et al. (2012) found that of 1737 young children diagnosed with ASD, 40% reached clinical levels on measures of ADHD.

While the link between ASD and ADHD has received the most research attention, we note that many other problems arise in children and youth with developmental disabilities, either comorbid with ADHD or separately, including anxiety, depression, behavior problems, fewer adaptive skills, and overall poorer quality of life. When a child with ID or ASD manifests any of these comorbid behavior and/or mental disorders, the impact on parents and families becomes more severe. One clear indication is that primary care providers for children with developmental disorders should screen for symptoms of ADHD, other psychiatric disorders, behavior problems, and adaptive skill deficits in these children and consider these broader co-occurring problems when developing a care plan.

Increased impact on families. It is, then, common that when a child has a developmental disorder, many – indeed most – families will encounter additional child-rearing challenges beyond those in the core definitions of intellectual disability and/or autism spectrum disorder. These “collateral effects” from behavior disorder/mental health challenges have negative impacts on the child and also on the family, beyond – *and even greater than* – the impact of the disability itself. *Indeed, evidence supports the conclusion that the behavior disorder/mental health problems greatly overshadow the disability in the challenge facing families.* This section, then, considers studies by researchers who examined youth with a type of dual diagnosis serious enough to put limits on the youth’s opportunities. Our key focus is on the extent to which parenting stress, parent psychological adjustment, and family functioning are impacted by rearing a child with a comorbid developmental disability and behavior/mental disorder.

Looking back: McIntyre et al. (2002) assessed collateral impacts on the family by looking back. They conducted lengthy interviews with the mothers of 103 young adults with severe ID. They assessed not only the young adult’s adaptive functioning, maladaptive behavior, and mental health problems but also the extent to which these had in the past and presently have negative impacts on the family. Behavior and/or mental health problems significantly increased mothers’ perceived negative impact of the YA on the family and predicted the family’s steps toward seeking out-of-home placement.

At the same time (2002) Baker et al., at three universities, examined 225 3-year-old children with developmental delays or typical cognitive development. Parents completed the *Child Behavior Checklist* (CBCL; Achenbach and Edelbrock 2002), a measure of child behavior problems that yields diagnostic categories. They also completed a self-report measure of parenting stress called the *Family Impact Questionnaire* (Donenberg and Baker 1993). Total behavior problems scores within the designated clinical range were three (mothers’ scores) to four (fathers’ scores) times as likely for children with developmental delays.

Collateral effects of disability and behavior disorders were already evident at this young age, as parenting stress scores were significantly higher in families of the children with both developmental delays and clinical level behavior problems. Regression analyses revealed that the extent of child behavior problems was a much stronger contributor to parenting stress than was the child’s cognitive delay, a surprising finding that now has been replicated in many other studies (e.g., McStay et al. 2013).

Other investigators have underscored, and expanded upon, the adverse effects on parents and families from the frequent collateral effects of a child’s developmental disability and accompanying internalizing (e.g., anxiety) or externalizing (e.g., attention or conduct problems) disorders. To cite a few: Yorke et al. (2018) disaggregated child externalizing and internalizing problems and showed that parents’ mental health problems and parenting stress were not solely driven by either, but, rather, that both are causal factors. Carlsson et al. (2013) expanded the scope of outcome from behavior/mental health disorders in young children with ASD, reporting heightened parenting stress from other domains, including comorbid language problems, below average motor function, and severe hyperactivity. Other researchers have found decreased physical health in mothers parenting a child with comorbid disorders (Benson 2017).

In sum, parents and families raising a child with a developmental disorder often face the dual challenge of also coping with comorbid behavior problems/mental health disorder and related effects. As we have noted, the comorbid behavior/mental health conditions often present more difficulties for the child and the family than the developmental disorder. We have spoken mainly of parenting stress, but there are also wide-ranging daily challenges that limit social, educational, employment, and other opportunities for the child, siblings, and parents. Fortunately, there are today many available services that provide support, respite, guidance, and more. What is most encouraging is that so many families have found ways to accept the child’s disabilities and integrate him or her into family life. Our next

section will look at positive parent and family characteristics that normalize and embrace disability.

Dispositional Optimism and Positive Beliefs: Buffering the Impact of Child Developmental Disability and Comorbid Behavior/Mental Health Challenges on Parents and Family Well-Being

Optimists have a favorable outlook on life: they believe that good rather than bad things will happen to them (Olason and Roger 2001).

Over 35 years ago, Crnic et al. (1983) proposed a model for the study of families that presented a more positive view of family outcome, to balance the more negative perspectives so predominant in the literature at that time. Parents have within themselves many ways of coping with child-rearing challenges. We will focus here on parent cognitions, especially dispositional optimism and positive beliefs, as they moderate the collateral effects of child developmental disorder when combined with behavioral/mental health challenges.

We consider here beliefs that will ease child-rearing challenges, drawing primarily on studies of children with dual diagnoses of developmental disability and behavior/mental health disorders (Blacher et al. 2013a). One important finding to remember has been that when causes of increased parenting stress have been parsed into (a) the child's developmental disability itself or (b) the comorbid child behavior problems/mental disorders, the latter accounted for most of the variance (Baker et al. 2002).

Dispositional optimism. Scheier and Carver (1985) proposed dispositional optimism as a relatively stable personality trait that leads to more positive coping with adversity or a "general positive expectation regarding future events regardless of one's control over the outcome" (Scheier et al. 1994). Optimists have a favorable outlook on life: they believe that good rather than bad things will happen to them. Our use of "optimistic" in what follows is referring to dispositional optimism. To maintain such positive beliefs, optimists rely on positive evaluation of the social context and its ability to provide necessary support. Dispositional optimism leads parents to have

an attentional bias toward their children's positive behaviors (Segerstrom 2001).

While dispositional optimism is a general positive expectation about future events, self-mastery is the belief in one's control over specific events. Paczkowski and Baker (2008) examined the role of self-mastery and then examined self-mastery and dispositional optimism together ("positive beliefs"). One's perception of control over life events and one's optimism about the future may be accurate reflections of the true degree of control one has or of the actual likelihood of future positive events. However, many people display unrealistic beliefs about the degree to which they control events in their environments. Regardless, optimism, no matter how unwarranted the positive outlook is, will lead to better coping with child challenges.

Measuring dispositional optimism. The widely used research measure of optimism is the self-report *Life Orientation Test - Revised* (LOT-R), a 6-item self-report scale with four additional filler items (Scheier et al. 1994). Sample items are "In uncertain times, I usually expect the best" and "If something can go wrong for me, it will" (reverse coded). Respondents indicate the extent of agreement on a 5-point Likert scale from 0 (Definitely disagree) to 4 (Definitely agree). The LOT-R has high internal reliability. In one study, parent optimism scores at child ages 3, 6, and 9 years were quite stable across these assessments. In that study, mean optimism scores for parents of children with ID or TD did not differ significantly (Blacher et al. 2013b).

Dispositional optimism further explored. This personality trait of optimism, which is present early in life, is associated with more problem-focused coping, such as seeking social support, actively solving problems, and maintaining a positive outlook on life. The relationship between dispositional optimism and more positive outcomes has been supported by considerable research. In one study higher optimism related to increased positive affect, greater life satisfaction, and psychological well-being (Ekas et al. 2010). In another, optimistic parents of children with a developmental disorder were more likely to engage in problem-solving and seeking social

support (Khan and Alam 2016). In other studies, more optimistic parents were effectively modulating their anger and patience, managing their children more appropriately, and developing more effective coping strategies (Koenig et al. 2010). In short, dispositional optimism and positive beliefs are protective factors for mothers' and fathers' parenting and well-being.

Dispositional optimism, then, moderates the effect of child challenges on parents' psychological distress. As child challenges increase, optimism has a progressively greater benefit. Many studies have found higher dispositional optimism to be related to increased positive and decreased negative parenting. One found that inner-city mothers with higher optimism had more positive parenting (Jones et al. 2002). Ellingsen et al. (2013, 2014) examined parent variables that predicted changes in resilient parenting from ages 3 to 5 and 5 to 8 years. Mothers' education and optimism were protective factors for positive parenting from child ages 3 to 5 and for resilient parenting from child age 5 to 8. Taylor (2010) more generally showed that optimism helps parents maintain positive parenting during adverse times.

Positive beliefs. Related to optimism are parents' positive beliefs about the child and child-rearing. Hastings and Taunt (2002) found that parents spoke to benefits they derived from raising a child with ID or ASD; these included having increased sensitivity and tolerance, a changed perspective on life, improved family dynamics, and opportunities to learn new information. Beighton and Wills (2019) reviewed 22 studies across many countries, reporting how parents described the positive aspects of parenting their child with ID. They concluded that caregivers reporting positive aspects had better self-reported health, fewer depressive symptoms, higher caregiving competence, and greater family adjustment. Fully 75% of mothers and 67% of fathers reported experiencing personal/emotional growth and increased benefit finding. Greater social support led to more positive parent perceptions.

Research published over the past two decades has underscored the power of positivity, whether in the form of positive perceptions, positive

coping, or optimism. To maintain such positive beliefs, optimists rely on a sense of positive evaluation of the social context and its ability to provide necessary support. Optimists are more likely to engage in problem-solving and seeking social support. They effectively modulate their anger and impatience, as well as manage their children more appropriately. Problem-focused coping which emphasizes efforts to seek social support, actively solve the problem, and maintain a positive outlook on life is most adaptive.

Positive impact/positive perceptions. Positive impact can be assessed by a subscale of the *Family Impact Questionnaire* (FIQ; Donenberg and Baker 1993). This 7-item scale is introduced by "We would like to know what impact your child has had on your family compared to the impact other children his/her age have on their families." Sample items are: *I enjoy the time I spend with my child more*, and *My child makes me feel more energetic*. Perceived positive impact was assessed with parents of 92 children with developmental delay (DD) and 122 TD children at ages 3, 4, and 5 years (Blacher and Baker 2007). Even with this large sample, there were no significant differences between mothers or fathers of DD and TD children. However positive perceptions did significantly lessen the relationship between child behavior problems and parenting stress.

We close with an illustration of how mothers' psychological symptoms (e.g., stress, depression) are increased with increasing child risk, but moderated by mothers' optimism (Blacher and Baker 2017) (Fig. 1). Families were assigned to one of three child categories of increasing risk to parent well-being: The child had neither disability nor disorder (Risk 0); had disability *or* disorder (Risk 1); or disability *and* disorder (Risk 2). Mothers' optimism scores were divided into thirds (high, medium, low optimism). Mother's self-reported psychological symptoms were derived from the Symptom Checklist (Derogatis and Savitz 2000). When child risk was low (0), mother's psychological symptoms were also low, and optimism did not matter. As child risk increased, mothers' psychological symptoms also increased. This was most dramatic for mothers with low optimism; mothers with high optimism demonstrated very

Collateral Effects of Youth Disruptive Behavior Disorders on Mothers' Psychological Distress: Intellectual Disability, or Typical Development,

Fig. 1 Mother psychological symptoms by youth risk and maternal optimism

Risk $F=12.99$, $p < .001$ Optimism $F=10.74$, $p < .001$; Risk X Optimism $F=2.63$, $p < .05$

few psychological symptoms. Statistically, main effects of risk and optimism were highly significant, and the risk x optimism interaction was also significant.

Risk $F = 12.99$, $p < 0.001$ Optimism $F = 10.74$, $p < 0.001$; Risk X Optimism $F = 2.63$, $p < 0.05$.

Future Directions

To date, the dominant theme in the literature on family impact of ASD, with or without comorbid ID, has been stress and overall negative effects. Clearly, children with ASD are at great risk of concomitant psychological disorders. Indeed, it is rare to find autism in the absence of other comorbidities (Gillberg and Fernell 2014). Happily, though, there is a trend of work focusing on more positive aspects of rearing a child with behavioral challenges, and these findings pertain to parents of children, youth, and young adults with ASD and comorbid disorders. We are hopeful that the empirical findings reported here will be translated into interventions for parents, in order to foster more adaptive outcomes.

College Transitional Programs

Ginny Hodge and Michael Storz
Chapel Haven, Inc, New Haven, CT, USA

Definition

College Transition Programs are specialized programs dedicated to helping young adults with ASD to have successful college experiences. The number of these programs has dramatically increased over recent years, and there are programs located across the United States.

Historical Background

The population of individuals with ASD has risen dramatically in the past three decades, from one in 10,000 individuals in the 1980s (Autism Science Foundation 2012) to 1 in 68 children in 2016, according to estimates from the CDC (2016). There has also been a shift in the characteristics of this population. In the years between 1966 and 1998, only about 20% of individuals with an autism diagnosis were found to have IQs in the average range (Fombonne 1999). As of 2010, nearly half of individuals with autism had IQs in

the average range (CDC 2014). In addition to this shift in cognitive ability of those with ASD diagnoses, more effective and widely available early intervention programs have emerged, leading to better outcomes among this group.

The increase in overall numbers of individuals diagnosed with ASD, coupled with this shift in IQ, has vastly increased the number of individuals on the autism spectrum who have the cognitive capacity for college-level academics. As identification of ASD among individuals with no intellectual disability has improved, it is likely that the numbers of college students with ASD will continue to rise (Barnhill 2014). These factors have all impacted the trajectory of the lives of individuals with ASD, leading to a higher level of participation in college environments.

A longitudinal study completed in 2007 revealed that individuals who were diagnosed with an autism spectrum disorder in childhood generally retained this diagnosis into adulthood (Cederlund et al. 2008). Adult outcomes for individuals with ASD have historically been troublesome. Of those individuals with an ASD diagnosis and cognitive abilities in the average range, only 27% achieved what would be described as a “good outcome” in adulthood (Cederlund et al. 2008). Due to the extremely small numbers of individuals with ASD who attended colleges and universities in the twentieth century, little to no historical data about college success exists.

Students with ASD who attended college in previous decades were generally supported through the department/personnel who supported students with any disability, and at many colleges and universities, this remains the case. Legislation such as the Americans with Disabilities Act (ADA 1990) and Section 504 of the Rehabilitation Act of 1973 mandated equal access for individuals with disabilities, as well as provision of certain accommodations. Passage of these laws resulted in an increase in the ability of individuals with a range of disabilities to access higher education. However, as the number of students with ASD who were both interested in and capable of completing a college education rose, programs emerged with their needs in mind. The first university-based program was the college program for students

with Asperger syndrome at Marshall University in Huntington, West Virginia. This program, founded in 2002, was initially developed by the West Virginia Autism Training Center located at Marshall to meet the needs of a single student (Ellison, M., personal communication, 1/11/2017). Due to a high level of demand, it rapidly expanded and remains a pioneering program in the field today.

Current Knowledge

Approximately 50,000 individuals with autism turn 18 each year (Roux et al. 2013), and that number continues to rise. Engagement in productive activities after high school remains a challenge for individuals with ASD. A study conducted in 2012 by Shattuck et al. revealed that 34.7% of individuals with ASD had attended college within 6 years after high school. More than 50% of the young adults with ASD had no participation whatsoever in employment or post-secondary education within the first 2 years after high school. College success for students with ASD has remained a challenge. Even among those students who participate in higher education, high levels of academic achievement and meeting graduation requirements has often been elusive. At the conclusion of Shattuck et al.'s study (2012), less than 20% of students who went directly from high school to a 4-year college had graduated or were on track to graduate.

At the time of this publication, there were at least 31 college transition programs for individuals with ASD known to be in existence in the United States (Barnhill 2016), with that number increasing each year. There are a range of types of programs and supports that are offered. There are some programs that provide individuals with ASD an opportunity to participate in program offerings based on a college campus, outside of the standard coursework that the college offers. Other programs provide supports to individuals as they participate in the standard coursework. Of these programs offering support to take credit-bearing coursework, there are some, such as the program at Marshall, that are operated by the hosting

university or a related entity. Other programs, such as Chapel Haven in New Haven, CT, and Tucson, AZ, are operated by nonprofit agencies and have supports available at multiple colleges and universities. And still others are for-profit corporations offering services at various locations around the United States.

There are varying levels of supports offered at these various programs as well. Some programs offer supports which focus predominantly on academic success, others also include a focus on peer relationships and social skill development, and a few provide a broad range of supports including academic, social, daily living skills, and career development. Most of these programs have oversight provided by a professional experienced in working with students with ASD. Many also have a range of professional staff, while others utilize graduate students from the university, or undergraduate students, often in peer mentor roles.

College transition programs often provide tutoring, organizational support, and/or support accessing on-campus academic resources to help students with ASD succeed in their classes. Some programs also offer supports such as social skills instruction, counseling, or behavioral consultation. Many offer assistance accessing activities with peers, including clubs, sports activities, and residential life activities. A few of the most comprehensive programs also offer supports within the individual's residential environment, whether that be in a college residence hall or elsewhere.

A recent study identified 31 institutions of higher education that provided support services for individuals with ASD beyond those typically offered by college or university disability offices (Barnhill 2016). Of 30 institutions that shared information about their practices for this study, the vast majority provided academic accommodations (e.g., extended time, tutoring, notetakers, etc.) as well as an assigned advisor. More than two thirds of these programs also provided peer mentoring and accommodations in the areas of life skills and social skills. The provision of support services was more variable. Approximately 50% provided social skills groups and 43% provided individual therapy, while just 17% used a

group therapy model and only 13% utilized non-therapeutic groups (Barnhill 2016).

Specifically tailored interventions can allow students with ASD to succeed in the college environment. It is imperative that students and families explore all available options in order to assess the “goodness of fit” of postsecondary programs (VanBergeijk et al. 2008). Finding a program that offers the necessary supports for an individual and also provides access to a college or university that meets the individual's academic needs can be daunting. Families and individuals with ASD may begin the process of searching for the right program significantly in advance of the individual reaching college age. The assistance of educational consultants and other professionals is sometimes sought. The West Virginia Autism Training Center offers a document entitled “Benchmarks of Effective Supports for College Students with Autism Spectrum Disorders” on their website. This document assists students and families in evaluating college transition programs supports as related to the needs of an individual student (Ellison et al. 2012).

Students participating in structured college transition programs have access to substantially more supports than individuals attending college without the assistance of such a program. Even with these supports in place, many individuals on the autism spectrum continue to face some challenges in the postsecondary environment. Challenges faced by college students with ASD include managing new situations and unexpected changes, social relationships, problems with information processing, and time management (Van Hees et al. 2015). They juggle challenges in both college life and basic independent living skills.

An additional consideration when students are exploring college transition programs is cost. A small number of programs are able to provide services at no additional cost to students, outside of college tuition, but the vast majority of support programs for students with ASD require additional tuition and/or fees, which can be significant and pose a barrier for many students and families. These fees may be as low as a few hundred dollars per semester, or up to tens of thousands of dollars

per semester, depending upon the types of supports offered.

The existence of college transition programs offer a path to postsecondary success that many students with ASD may not have otherwise. Selecting the right program, with an appropriate array of supports for an individual student can be life-changing. Anecdotal information and observations suggest that these programs lead to higher levels of college success for individuals with ASD, but thus far, there has been virtually no research done to investigate the success of these programs or of the specific components within these programs. Some programs, including Chapel Haven, have embarked on a path to collect data in order to empirically demonstrate outcomes of their transition programming.

Future Directions

As the rising numbers of individuals with ASD complete high school and begin to enter postsecondary educational institutions, the supports available to them will need to continue to expand to meet this increased need. There will likely be a broadening of supports to meet the unique needs of this population. In a recent survey, individuals with ASD identified that programs facilitating their success should have a personalized approach, a safe/transparent environment, academic accommodations, adequate psychosocial support, leisure activities, and a sufficient amount of rest. They also identified that coaching in education, student life, and daily living should be integral to their supports (Van Hees et al. 2015).

A large majority (79%) of individuals with autism spectrum disorders meet the criteria for a psychiatric disorder at some point in their adult life. These symptoms are most prevalent during the young adult years (Lever and Geurts 2016). These challenges need to be addressed simultaneously to academic and independent living challenges so that the individual may be successful in the college environment. It will be important for college transition programs in the future to continue to provide and/or expand access to these supports to facilitate student success. We have

little detailed empirical data about psychiatric challenges among this population however, so there is a need to continue to investigate to learn more about these challenges can be addressed (Howlin 2014; van Schalkwyk et al. 2016).

There is a dire need for more data and research regarding the types of supports that lead to success in the transition to college for individuals with ASD. As the need for supports have become apparent, many programs have emerged, but information on their effectiveness is scarce. Due to the lack of data on adult interventions in general, most of these programs have needed to rely on information about best practices for children in the development of their programs. Although there is often anecdotal information about what is and is not working for individual participants, there is a dearth of information regarding best practices in transition programming for college students with ASD. In a 2014 systematic review, Gelbar, Smith, and Reichow identified 20 articles, describing a total of 69 college students with ASD, only two of which were empirical studies (Gelbar et al. 2014).

It would be beneficial for the funding sources for college transition programs to be further explored and expanded, in order to allow a greater number of individuals to access these services. There is a significant disparity in college participation for young adults with ASD based upon family income. In a recent study, of those whose parents fell into the lowest identified income bracket, only 19% attended college, while 60% of those with parents in the highest income bracket attended college (Shattuck et al. 2012). Although this disparity certainly exists among young adults without ASD as well, the added expense of transition programming and supports creates an additional barrier for prospective college students from lower-income households.

Finally, as the effects of autism are not mitigated by college graduation, there is a need to explore ongoing adult services and successful transition to these services for many individuals who have participated in college transition programs. A large number of individuals, even those who have successfully completed college, will continue to require supports with various aspects

of adult life, from independent living to developing social networks to employment and career support.

Comic Strip Conversations

Brian Reichow

Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Anita Zucker Center for Excellence in Early Childhood Studies, University of Florida, Gainesville, FL, USA

Definition

Comic strip conversations are a social narrative that depicts or enhances a conversation or social situation between two individuals by specifying the underlying thought processes and/or communicative exchanges using line drawings incorporating thought bubbles, speaker bubbles, and other symbols. “Comic strip conversations systematically identify what people say and do, and emphasize *what people may be thinking*” (p. 1, Gray 1994).

Historical Background

Comic strip conversations were first described by Carol Gray in 1994 (Gray 1994) and are closely related to Gray’s Social Stories. Since then, little research has evaluated the efficacy of the intervention, and little development beyond what was initially described by Gray has occurred.

Rationale or Underlying Theory

A comic strip conversation is a type of social narrative. Other types of social narratives include Social Stories, cartooning, and Power Cards (Wragge 2011). A social narrative is a written description of various social situations that might

be problematic for an individual with an ASD. The narrative helps explain what typically occurs in a given social situation, thoughts other individuals might have, and how one is expected to act in a given situation. Comic strip conversations enhance a conversation between two individuals by specifying the underlying thought processes and/or communicative exchanges using line drawings incorporating thought bubbles, speaker bubbles, and other symbols. Through the incorporation of these items into a conversation, an individual with an ASD is provided a visual and concrete depiction of the conversation and/or social situation. Providing this pictorial depiction (representation) of an abstract social situation is thought to capitalize on the improved processing of visual information that many individuals with ASDs have. The exact mechanisms by which comic strip conversations and other social narratives are effective remain unknown.

Goals and Objectives

Comic strip conversations aim to help an individual with an ASD understand the underlying thought processes and/or communicative exchanges that occur during conversations and other social situations. Comic strip stories help provide a concrete depiction of the expectations of individuals in specific social situations and the impact that their actions can have on the thoughts of others in that situation, thereby providing the individual with ASD a scheme for improving their behavior in a social situation. Through the use of thought bubbles (described later), one is able to explicitly show a person’s thoughts, thus providing insight into their theory of mind, which is often a difficult area for individuals with ASD. Because comic strip conversations can provide this visual representation of theory of mind, this is also often a target of intervention.

Treatment Participants

Since there has been little empirical study of comic strip conversations, the following

parameters are based on recommendations based on the intervention's components and techniques. Comic strip conversations are likely to be most beneficial to individuals who have higher cognitive functioning skills across all ASD diagnoses. Although young children (e.g., children younger than 5 years) might benefit from comic strip conversations, the heavy emphasis on language and higher-order social thinking makes school-age children, adolescents, and adults to be the ages of individuals who are likely to receive the most benefit.

Treatment Procedures

Comic strip conversations are typically completed in a one-to-one child to therapist (teacher, parent, etc.) ratio. The intervention begins with the adult engaging in small talk to strengthen rapport. The child or therapist then begins the conversation by drawing a social scene involving multiple people. Multiple boxes (or pages) can be used if the scene involves multiple steps or situations. Speaker bubbles can be used to indicate what people are saying in the scene, and thought bubbles can be added to indicate what people are thinking (but not saying) during the scene. Thought bubbles provide a nice way for the therapist to provide perspective of what people are likely to be thinking but not necessarily saying during a situation exchange or interaction. After the therapist feels the child has processed the social situation and the perspectives of those involved, the therapist then can ask the child to summarize the situation and provide solutions to the problems the child is likely to face when they later participate in similar situations.

Efficacy Information

There have been no experimental studies presenting quantitative data demonstrating the efficacy of comic strip conversations for students with ASDs. Two reports (Pierson and Glaeser 2007; Rogers and Myles 2001) presented brief descriptions of the perceived efficacy of comic strip conversations that were used to increase

prosocial behaviors of individuals with ASDs. Pierson and Glaeser reported qualitative data suggesting comic strip conversations increased peer interactions and decreased loneliness for three children with ASDs. Rogers and Myles reported that comic strip conversations appeared to be more effective (as measured by teacher count of the number of redirections for desired behavior) than social stories for helping a 14-year-old boy with Asperger's disorder navigate to PE class. Clearly, more research on the efficacy of comic strip conversations is needed before the technique can be considered an evidence-based practice.

Outcome Measurement

Comic strip conversations are typically writing for individual children targeting specific behaviors. Therefore, outcome measurement is likely to focus on behavioral measures of the target behaviors. Since theory of mind is often targeted, some measures of theory of mind (e.g., faux pas tasks, strange stories, false-belief tasks) might be used to assess the impact of the intervention technique on this construct.

Qualifications of Treatment Providers

There are no formal qualifications (i.e., credentials, licensure) necessary for using comic strip conversations. There is a brief manual (Gray 1994) providing basic guidelines for using the intervention. Additional practice parameters have also been published (Glaeser et al. 2003; Rogers and Myles 2001). What is necessary is that the interventionist has knowledge about how social deficits in ASDs are manifested and how autism can limit an individual's ability to interpret social situations and function independently in a typical social milieu and the ability to integrate that knowledge into meaningful examples of how one can improve their social behavior. Parents, psychologists, special education teachers, and speech-language pathologists are typical groups of interventionists that might use comic strip conversations.

Common Disease-Common Variant Hypothesis

Paul El-Fishawy

State Laboratory, Child Study Center, Yale University, New Haven, CT, USA

Synonyms

CDCVH

Definition

The Common Disease-Common Variant Hypothesis (CDCVH) is a hypothesis that proposes if a disease that is heritable is common in the population (a prevalence greater than 1–5%), then the genetic contributors – specific variations in the genetic code – will also be common in the population. It makes this prediction for diseases whose genetic contribution is believed to come from multiple genes simultaneously, polygenic disorders. Autism is thought to be such a disorder.

The CDCVH is based on evidence from evolutionary theory, specifically that all humans today descended from a small population of roughly 10,000 individuals in Africa a relatively short time ago, approximately 100,000 years ago. Based on evidence about how frequently new mutations enter the population, it states that the extremely rapid population expansion that has occurred over a short period disseminated disease alleles (genetic changes or variations) that were common in the original population at a far greater rate than new mutations have introduced such alleles. Therefore, genetically influenced

diseases that are common today should be the result of disease alleles that were common in the original population and should still be common in today's population, as they would have been widely distributed by the massive population explosion faster than new disease alleles could be introduced.

Several types of studies can be undertaken to identify common genetic variants contributing to common disease. The most reliable of these is called a genome-wide association study (GWAS). These evaluate common genetic variations, often in the form of single nucleotide polymorphisms (SNPs), at every gene in the genome simultaneously. Such studies have reproducibly identified common genetic risks for a wide range of common medical conditions. However, there have only been a small number of cases in which these common genetic variations explain a substantial proportion of the overall predicted genetic risks for the disorder. As a result, some have put forth a competing hypothesis, the Common Disease-Rare Variant Hypothesis, that states that common diseases may be explained by a multiplicity of individually rare disease alleles in the population.

With regard to autism, several GWAS studies have been conducted, and, so far, three SNPs have been found that meet criteria for significance, taking into account the fact that the entire genome has been evaluated simultaneously. However, none of the three studies replicate the others' findings, and combining the data from all three decreases the evidence for any one of these genetic markers being associated with autism spectrum disorders. While it is expected that common genetic polymorphisms carry risks for ASD, there is not yet agreement that any particular variation or gene has been definitively identified.

Common Disease-Rare Variant Hypothesis

Paul El-Fishawy

State Laboratory, Child Study Center, Yale University, New Haven, CT, USA

Definition

The Common Disease-Rare Variant Hypothesis (CDRVH) hypothesizes that if a disease with genetic causes is common in the population (a prevalence greater than 1–5%), then the genetic causes – specific genetic errors (genetic variants or disease alleles) – will not necessarily be found to be common in the population as suggested by the competing Common Disease-Common Variant Hypothesis (CDCVH) but rather will be comprised of a multiplicity of risk alleles, each of

which is individually rare in the population. It makes this prediction for diseases whose genetic contribution is believed to come from multiple genes simultaneously, polygenic disorders. Autism is thought to be such a disorder.

The CDRVH states that common polygenic disorders may reflect the convergence of multiple, rare variations in the same gene (allelic heterogeneity) or multiple genes (locus heterogeneity). Given a sufficiently large number of disease alleles that could be involved, individually rare mutations could accumulate in the population and account for a significant proportion of a common disorder. Such variation could be transmitted from generation to generation or occur as new mutations (also known as de novo mutation). The latter would give rise to a pattern of inheritance prevalent in autism, where cases are often sporadic (only a single child is affected in a family) and identical (monozygotic) twins share the disorder much more frequently than nonidentical (dizygotic twins).

Proponents of the CDRVH have recently been able to cite considerable empiric evidence supporting this hypothesis. First, to date, it has been difficult to confirm the presence of common variants contributing risk for ASD. Several contemporary well-controlled association studies have implicated biologically plausible candidate genes, including the *MET oncogene*, *Contact-Associated Protein Like 2*, *Cadherin 9* and *Cadherin 10*, *Semaphorin 5A*, and *MACRO domain containing 2* (State and Levitt 2011). However, at present, the field has not reached a clear consensus about which of these genes or loci carry definitive risks. More importantly, were all of these association signals to be confirmed, they would nonetheless account for only a small proportion of the predicted genetic contribution to ASD. Perhaps, more importantly, to date, studies of rare variation have begun to demonstrate that a measurable proportion of the ASD-affected population carries very rare genetic mutations, either in the structure or sequence of the DNA, contributing biological effects that are much larger than those so far associated with common variants. For example, current estimates are that 5–10% of affected

individuals carry large de novo copy number variations (CNVs) that substantially increase the risk for ASD (and other neurodevelopmental disorders). In addition, a measurable proportion of individuals with ASD can be found to have mutations in *FMRP*, *TSC-1*, *TSC-2*, or other rare so-called monogenic forms of autism. Finally, with the advent of new DNA sequencing technology, it is anticipated that additional individuals will be found carrying rare and de novo single nucleotide variants (SNVs) contributing relatively large risks. All told these findings provide substantial evidence in favor of the CDRVH in a proportion of individuals with social disability. It is important to recall, however, that in a genetically heterogeneous disorder such as autism, the contribution of rare variants does not rule out the potential contribution of common variants, either with respect to etiology or as a factor modifying other genetic and environmental risks.

Communication and Symbolic Behavior Scale

M. S. Hope Morris

Communication Sciences and Disorders, The
University of Vermont, Burlington, VT, USA

Synonyms

CSBS; CSBS-DP

Description

The *Communication Symbolic and Behavior Scales-Normed Edition* (CSBS; Wetherby and Prizant 1993) is a norm-referenced, standardized test designed to assess infants, toddlers, and pre-schoolers that are at risk for communication delays. In addition, this measure is used to establish a profile of communicative, symbolic, and social-affective functioning of a child, to monitor behavior change over time, and to provide a direction for intervention. The assessment surveys both language skills and symbolic development, including gestures, facial expressions, and play, using 22 5-point rating scales (18 in the communicative domain, 4 in the symbolic domain). This measure can be used with infants and toddlers with functional communication ages of 6–24 months and children up to 72 months exhibiting atypical development. It can be administered by a speech-language pathologist (SLP), psychologist, early interventionist, and other professional trained to work with developmentally young children. As a part of this assessment, parents or caregivers complete a Caregiver Questionnaire, providing background information that can be utilized as a baseline for evaluation. The evaluator samples the child's communicative behaviors in structured and unstructured play-based activities in the child's natural environment. Communicative temptations, sharing books, symbolic play, language comprehension, and constructive play activities are utilized to encourage spontaneous communicative and play behaviors. Ideally, the

sample is videotaped, so as to continue natural interactions during the assessment and to ensure accurate scoring and analysis. This test takes approximately 1 hour to administer and 1 hour to score the videotape. The Caregiver Questionnaire takes about 15 min to complete.

The *Communication Symbolic and Behavior Scales-Developmental Profile* (CSBS-DP; Wetherby and Prizant 2002) is the companion test to the CSBS that is designed to evaluate communication and symbolic abilities of children in the same age range as the CSBS-Normed Edition. However, this test is intended as a guide to indicate areas that may need further assessment or to monitor behavior change. This test includes a one-page Infant-Toddler Checklist for screening, a four-page Caregiver Questionnaire, and Behavior Sample, which is a shorter, more streamlined version of the CSBS-Normed Edition. It should be noted that the CSBS-DP should not be used alone for decisions about program planning. The CSBS-Normed Edition is a more in-depth tool and is designed for making program-planning decisions. The CSBS-DP takes about 30 min to administer, and the Behavior Sample can be scored during the sample or videotaped. The Infant-Toddler Checklist can be completed in 5–10 min, and the Caregiver Questionnaire can be completed in about 20 min.

Historical Background

In 1986, the passage of the Education of the Handicapped Act, Amendments of 1986 (PL 99-457) provided funds to states that chose to develop and implement early identification and intervention services for infants and toddlers beginning in 1991. This included children that were at high risk or children up to their third birthday that had identified disabilities, including delays in speech and language. Often, speech-language delay is the first symptom of developmental delay that parents or professionals notice. Unfortunately, however, early identification was compromised by the limited number of standardized tools for assessing very young children. Early identification of these delays or lack of speech-

language development is crucial, as typical early language development occurs between 12 and 20 months of age. The detrimental effects of early speech and language disorders on later development of peer relations, educational success, as well as emotional and behavioral development have also been well documented in the research (Prizant et al. 1990). Most formal tests used to measure children's communication abilities are clinician-directed and focus on the child as a responder. There were few tests available that sampled communication, especially communicative intent, in a naturalistic way. Communication sampling is needed to supplement formal testing for children who are preverbal or at an early verbal communication stage (Wetherby et al. 1988). Therefore, the CSBS was developed to allow for an informal communication sample. With the implementation of PL 99-457, it was critical that clinicians utilize informal sampling procedures in their assessment process.

The sampling procedures were developed and refined over a 10-year period. Pragmatic and social interactive theories from the 1970s and 1980s (Bloom and Lahey 1978) were utilized to make changes to the sampling procedures. Procedures including the presentation of communicative temptations or structured situations that encourage or entice a child to communicate were adapted from informal procedures to sample communication (Wetherby and Prizant 1989). This included an assessment of both communicative functions and communicative means. Sharing books, which was a temptation originally reported by Wetherby and Prutting (1984), was later considered separate from the communicative temptations, as it is less structured than the other included temptations. Reciprocity and social-affective signaling are also assessed as a part of this tool. Addition of these areas of assessment was based on the work of Stern (1985) and Tronick (1989) in socioemotional development. The communication sample provides a way to measure expressive language abilities, and a small measure of language comprehension was also added. These items were adapted from the work of Miller, Chapman, Branston, and Reichle (1980). Play skills, both symbolic and

constructive, were included in the sample, and toy sets were chosen for children that were developmentally appropriate for children 8 months to 24 months. The development of the symbolic scales was influenced by the model for emergence of symbols (Bates 1979) and based on theories of Piaget (Wetherby 1991).

The *CSBS-DP* (Wetherby and Prizant 2002) *Infant-Toddler Checklist* and the *CSBS-DP Caregiver Questionnaire* were adapted from the *CSBS Caregiver Questionnaire* (Wetherby and Prizant 1993) and from research on the *MacArthur Communicative Development Inventories* (CDI; Fenson et al. 1993, 1994). Studies indicate that parent report is a reliable measure of communication development, and a checklist format was chosen, as this method is more accurate than a diary or free-form format (Fenson et al. 1993). The items on the *CSBS-DP Caregiver Questionnaire* were based on the *CSBS-Normed Edition Caregiver Questionnaire* (Wetherby and Prizant 1993). The questions on the *CSBS-DP Caregiver Questionnaire* are meant to gather similar information to that which is gathered from the Behavior Sample. The words expressed and understood were based on the work of Fenson et al. (1994) and were the first 36 words reported with highest frequency on the MacArthur CDI. The CSBS-DP Behavior Sample was based on the CSBS Behavior Sample (Wetherby and Prizant 1993). However, it was modified by reducing the length of the sample. The scoring procedures were reduced from 23 to 20 scales, which simplified the scoring and enabled the evaluator to score during the observed interactions. Nineteen of the 20 scales were derived from the CSBS; however, the gaze/point-following scale was added based on research findings from Mundy, Kasari, Sigman, and Ruskin (1995).

Psychometric Data

The CSBS-Normed Edition (Wetherby and Prizant 1993) was developed and tested over several years with both normally developing children and children with language delays. This research edition of this test was standardized in 1990 and

1991. The videotaped samples were scored by a group of raters that were trained by the authors. Before beginning the rating for the norming study, they rated two additional tapes to calibrate with ratings of an experienced coder. The samples were taken for 282 children from 24 sites in the United States. The norming sample was weighted for scaling and norming analyses. Information about the sample provided in the manual includes age in months, linguistic stage, gender, race, and Spanish origin. Since the CSBS was intended to monitor a child's progress over several months, one-third of the sample were retested once within 2–3 months of the first administration.

Norms were developed by making the 22 scales comparable by converting individual raw scores to a common metric based on the sample. This was done by deriving percentile ranks of raw scores on each scale based on the frequency distributions of these scores for the weighted sample between 8 and 24 months of age. Cluster scores were established that were based on summing of the scaled scores. The scaled scores for the 18 communication scales were summed to create a larger cluster score, the communication composite. The communication score and all cluster scores are expressed as percentile ranks. Means and standard deviations of raw scores and sums of scaled scores by language age and total unweighted scores are provided in the manual. Reliability of this measure is reported using four common methods. Internal consistency, the degree to which the parts of the instrument measure the same characteristic, yielded a coefficient of 0.91 for the entire sample and 0.84 for children at the multiword stage. Stability, the consistency of the test and retest results for individual test participants whose performance has not changed, is provided. Test-retest scores are provided for all age intervals, including shorter intervals (less than 2 months) and longer intervals (greater than 2 months). Correlations between the test and retest scores for the shorter and longer interval subgroups are also provided. Taken together, this information indicates that the CSBS produces relatively stable rankings when children make significant improvements over shorter periods of time. Interrater reliability coefficients are also

provided. Raters following the CSBS training steps can achieve good agreement with other raters and experienced raters. Standard errors of measurement (SEMs) are provided for all cluster standard scores and communication-composite scores, along with details on confidence ranges. Demonstration of validity is provided, including face validity/ecological validity, criterion-related validity, and construct validity. Further, a complete assessment of gender differences in test outcomes is included in the manual. Studies of the CSBS demonstrate sensitivity and valid norms (Goodwyn and Cruz 1997) and suggest that the instrument has good predictive validity (McCathren et al. 2000).

The CSBS-DP (Wetherby and Prizant 2002) Preliminary Research Edition was developed and field tested with children younger than 24 months of age and was standardized between 1997 and 2000. Collection of Infant-Toddler Checklists, Caregiver Questionnaires, and Behavior Samples was used to derive norms. Raters were trained in the same way as was utilized for the norming of the CSBS. A total of 2,188 Infant-Toddler Checklists, 790 Caregiver Questionnaires, and 337 Behavior Samples were included for the standardization sample from eight sites in the United States and two sites in Canada. A majority of the United States' sample was recruited primarily from Tallahassee, Florida; therefore, the sample is not nationally representative. Information about the sample by age, gender, race and ethnicity, and parent age and ethnicity is included in the manual. Norms were procedurally derived in the same way as the CSBS. All reliability measures including internal consistency, SEMs and confidence intervals, test-retest reliability, and interrater reliability are included in the manual. Validity measures including content, face, construct, criterion, concurrent, and predictive validity are provided. The CSBS-DP shows good reliability and validity, indicating it is a good screening and evaluation tool for use with children between 6 and 24 months of age. Recent research indicates the concurrent and predictive validity of this instrument to be strong, and the findings support the use of this instrument in the screening and evaluation of young children (Wetherby et al. 2003).

Clinical Uses

The CSBS-Normed Edition (Wetherby and Prizant 1993) was designed to be used for early identification of children who have or are at risk for developing communication impairment. In addition, it was intended to establish a profile of communication, symbolic, and social-affective functioning. For this reason, the test helps early intervention providers to gauge further evaluation needs, to prioritize intervention goals, and to monitor progress. In the manual, there are guidelines for using the results of this profile in intervention planning, goal setting, and designating intervention contexts. Areas addressed include expanding the use of social-affective signals, enhancing reciprocity, expanding the range of communicative functions, increasing the sophistication of communicative means, and enhancing symbolic level. The use of this profile is recommended to assign relative strengths and challenges in the areas listed above and to provide an individualized approach to prioritizing goals. It is suggested that the communicative profile be compared to the symbolic profile and to design-focused activities utilizing developmentally age-appropriate toys and objects. The child's behavior displayed during the structured activities of the CSBS should be compared to the child's functioning in less structured environments. The authors suggest that activities that contain increased communicative demands should be planned with the child's strengths in mind. Naturalistic activities that allow for generalization of learning and communication skills are also recommended. Since the CSBS-DP (Wetherby and Prizant 2002) is intended as a guide to indicate areas that may need further assessment or to monitor change in behaviors, the CSBS-DP should not be used alone for decisions about program planning.

CSBS Communication and Symbolic Behavior
Scales-Normed Edition

Description

The Communication and Symbolic Behavior Scales (CSBS; Wetherby and Prizant 2003) looks at the communicative, social-affective, and

symbolic abilities of children whose functional communication age is between 8 months and 2 years. Its purpose is to assess infants, toddlers, and preschool children, and it may be used with children whose chronological age ranges from about 8 months to 5–6 years, if their developmental age is younger than 24 months. The CSBS provides quantitative and qualitative information about a child's communicative and symbolic abilities.

The CSBS contains three formal tests: the CSBS Caregiver Questionnaire, the CSBS Behavior Sample, and the Caregiver Perception Rating form. The CSBS Caregiver Questionnaire gains information from the caregiver regarding the child's communication and symbolic abilities and can be administered prior to the child's direct assessment. The questionnaire can be completed in about 15–20 min. The CSBS Behavior Sample is a play-based sampling procedure. It is broken up into six sampling contexts: warm-up, communicative temptations, sharing books, symbolic play probes, language comprehension probes, and constructive play probes. This takes about 1 h to complete and must be videotaped to complete scoring. A trained evaluator can then score the videotape in about 1 h. Immediately following the Behavior Sample, the caregiver should be asked to complete the Caregiver Perception Rating form. The caregiver rates the typicality of their child's behavior as observed during the Behavior Sample. The examiner may choose to interview the caregiver using this form as an alternative option.

The CSBS kit includes the CSBS Manual, a carrying bag with materials for the CSBS Behavior Sample, two instructional videotapes for the Behavior Sample that demonstrate the sampling procedures and scoring guidelines, Record Forms for scoring and reporting results, and the CSBS Caregiver Questionnaire. The materials included that are used during the CSBS Behavior Sample are action-based toys to get spontaneous communication, books for young children, and play materials that are used to see how a child uses and plays with objects symbolically and constructively.

The behaviors observed during the CSBS Behavior Sample are rated according to

22 5-point scales. These scales measure the following parameters, which are summarized in seven cluster scores: Communicative Function (scales 1–3) which examines (1) behavior regulation, (2) joint attention, and (3) sociability of communicative function; Communicative Means-Gestural (scales 4–6) which examines (4) conventional gestures, (5) distal hand gestures, and (6) coordination of gestures and vocalizations; Communicative Means-Vocal (scales 7–10) which examines (7) vocal acts without gestures, (8) inventory of different consonants, (9) syllables with consonants, and (10) multisyllables; Communicative Means-Verbal (scales 11–12) which examines (11) inventory of different words expressed and (12) inventory of different word combinations; Reciprocity (scales 13–15) which examines (13) respondent acts, (14) rate of communicative acts per minute, and (15) repair strategies; Social-Affective Signaling (scales 16–18) which examines (16) gaze shifts, (17) shared positive affect, and (18) episodes of negative affect; and Symbolic Behavior (scales 19–22) which examines (19) language comprehension, (20) inventory of different action schemes, (21) complexity of action schemes, and (22) constructive play.

The CSBS records three types of scores: raw scores, scaled scores, and normed scores. Raw scores and equivalent scaled scores are reported for the 22 CSBS Behavior Sample scales. Converting raw scores to scaled scores can be done using the Record Form. The scaled scores have a mean of 3 and a standard deviation of 1. Normed scores are reported for the seven clusters and for the communication composite score. Normed scores reflect the performance of children in the standardization sample both by 1-month intervals from 8 to 24 months and by language stage from prelinguistic to multiword. The Communication Composite is a sum of the scaled scores for scales 1–18. The scaled scores of the Communication Composite must be converted to an age-based or stage-based percentile rank and standard score scale that has a mean of 10 and a standard deviation of 3. Since the Communication

Composite scores have a large range and precision, the composite may also be converted to an expanded standard score scale that is widely used for composite scores on other test batteries with a mean of 100 and a standard deviation of 15. The CSBS Caregiver Questionnaire reports cluster raw scores for emotion and eye gaze, communication, gestures, sounds, words, understanding, and object use. The Caregiver Questionnaire also reports a social composite score, a speech composite score, and a symbolic composite score. The social composite score is a sum of the raw scores for emotion and eye gaze, communication, and gestures. The speech composite score is a sum of the raw scores for sounds and words. The symbolic composite score is a sum of the raw scores for understanding and object use.

Historical Background

The purpose of developing the CSBS was to provide an assessment tool for young children that were more representative of current research to identify and assess language and communication delays and disorders at an early age. As stated in the Individuals with Disabilities Education Act (IDEA) Amendments of 1991, and the Handicapped Act Amendments of 1986, a priority is to provide early identification and intervention services for at-risk infants and toddlers. The US Department of Education (1987) note that about 70% of preschool children with developmental disabilities have language and communication disorders, which highlights the need to develop assessments aimed toward the early identification of these children. Early identification and appropriate interventions can be an overarching factor to a child's future educational achievements and overall development (Wetherby and Prizant 2003). The most widely used communication and language assessment instruments for prelinguistic and early linguistic children emphasize the form of communication, rather than the intentions that are expressed with these forms. Previously used instruments are mostly clinician-

directed, limiting the observations of initiated and spontaneous communication used by a child. Language sampling has become more widely used in place of formal language measures for children who engage in conversation. Similarly, communication sampling can be used to supplement children in the preverbal or early verbal stages as it provides a naturalistic environment for assessment (Wetherby and Prizant 2003). This need brought forth the development of the current version of the CSBS that was first made as an informal procedure for sampling communication with preverbal children. The sampling procedures in the CSBS derived from pragmatic and social interaction theories that aimed to mirror a natural, ongoing adult-child interaction, to provide many opportunities for multiple communicative behaviors. The assessment was standardized and normed in response to the need for a more naturalistic assessment environment and the implementation of the IDEA principles to evaluate young children (Wetherby and Prizant 2003).

An initial version of the Communication and Symbolic Behavior Scales-Normed Edition was published in 1993. The previous version of the complete assessment has been changed over time, as scales that proved to be less reliable or discriminating were removed or revised. The Communication and Symbolic Behavior Scales-Developmental Profile (CSBS-DP) was then published in 2002; it is designed as a shortened version of the assessment and includes an Infant-Toddler Checklist. The Communication and Symbolic Behavior Scales-Normed Edition (2003) is the current version of the test that is commonly administered today.

Psychometric Data

The CSBS was standardized in 1990 and 1991, collecting behavior samples of communication and symbolic behaviors from typically developing children and children with delays. Professional scorers were trained to analyze and rate communication and symbolic behavior through

videotaped behavior samples gathered from 282 children. This sample was used to create the norms for the assessment. Children in the standardization sample were recognized by their linguistic stage, gender, race, and Spanish origin. Based on the age of the children in the sample, standard deviations and percentile ranks were created to indicate the level of performance at each linguistic stage. Reliability is reported through measures of internal consistency, stability, and interrater reliability. The internal consistency coefficients reported for the CSBS range from a low of 0.17 for Social-Affective Signaling to a high of 0.91 for Communicative Means-Vocal. The coefficient for the composite is 0.91, indicating strong internal consistency for a total score. Stability was assessed on 66 of the total children participants through a process of test-retest. As expected, correlation of scores was higher for shorter intervals, and effect sizes for the 22 scales are provided, revealing small to medium changes. The authors suggest these changes are likely due to natural period of growth. The interrater reliability was demonstrated by comparing the ratings of 22 children as assessed by 3 raters, which showed good agreement, ranging from 0.83 to 0.90. Standard error of measurement has been calculated and provided for all cluster standard scores as well as the composite score. The construct validity confirms patterns of scores that increased on nearly all 22 scales across selected age intervals, aligning to established developmental expectations. The established means and standard deviations from the raw scores are consistent with known patterns for improvement in communication and symbolic behaviors during the period of early development.

Clinical Uses

The CSBS can be used for clinical purposes by providing quantitative and qualitative information of a child's communicative, social-affective, and symbolic abilities between the ages of 8 months and 2 years. Specific strengths of the assessment

include the ability to capture observation and measurement in the areas of joint attention and intentional communicating. A unique feature of this assessment is that it provides a variety of opportunities for spontaneous initiations of communication, including acts for initiating joint attention (Dos Santos 2009). Joint attention and intentional communication are key areas of deficit in individuals with ASD. The CSBS is a sensitive measure to specific social deficits observed in children with ASD (Wetherby and Prizant 2002).

Research on children with autism spectrum disorder (ASD) has shown how the clinical use of CSBS can be helpful in early diagnoses of ASD given its focus on joint attention and initiating behaviors. For example, it is known that there is an early deficit in shared attention in children with ASD in the second year of life showing lack of appropriate gaze and fewer gaze shifts compared with children with other developmental delays (DD) and typically developing (TD) children (Charman et al. 1997; Swettenham et al. 1998; Wetherby et al. 2004, 2007; Shumway and Wetherby 2009). Additionally, children with ASD evidence a lack of communication involving coordination of at least three of the following: gaze, facial expression, gesture, and sound (Wetherby et al. 2004; Shumway and Wetherby 2009). These well-established early signs of ASD in young children can all be measured through the CSBS and thus has the potential to assist in early diagnosis.

This assessment allows a child's communication and symbolic behavior, which can potentially be missed in other communication assessments, to be measured in different areas based on a clinician's perspective as well as the parent and/or caregiver's perspective. The in-depth nature of this assessment provides quantitative and qualitative information about the child's abilities. The assessment can be administered in a naturalistic environment to observe the child's natural play and allows for multiple developmental domains to be observed in one sitting through an hour of play.

This assessment may take a long time to score based on the video of the Behavior Sample. Fortunately, the authors have developed the CSBS-DP to create a shorter and easier to use tool to

screen and assess young children for early delays, whereas the full CSBS assessment takes twice as long to administer and score and does not provide a checklist that can be used as a screening tool by other medical professionals. The Infant-Toddler Checklist found in the CSBS-DP can be used in clinical practice by a variety of health professionals such as pediatricians and child health nurses to identify infants and toddlers most at risk for a communication delay that may require a referral and further assessment (Eadia et al. 2010). Further research on the CSBS-Normed Edition (2003) would be beneficial to account for the limitations of the assessment and to look at further clinical uses.

future communicative success. The goal of communication assessment is to evaluate a child's current level of communicative skills across various settings and with different partners. Factors included in the assessment of communication are engagement and attention skills, nonverbal behaviors and gestures, and speech and language form and content. Since communication difficulties and pragmatic challenges plague the ability of children with autism to engage in reciprocal exchanges with their communicative partners, it is important to create profiles of communication strengths and challenges to increase understanding of the critical connections between assessment and intervention planning.

There are several screening and diagnostic tools specific to communication that can be used to assess a broad range of skills in children with autism spectrum disorders (ASD). Comprehensive measures are designed to detect problems across speech and language domains, including:

- Receptive and expressive semantic development (assessing vocabulary understanding and expression)
- Receptive and expressive morphosyntactic development (assessing the ability to understand and produce words and sentences)
- Articulation (assessing speech sound production)
- Phonology (assessing the ability to use speech sounds in systematically organized manner)
- Fluency (assessing the smoothness and flow of producing speech)
- Cognitive processes (assessing working memory skills important to the development of language)
- Metalinguistic processes (assessing rhyming and word segmentation abilities critical to the development of language and literacy)

Notably, many communication assessment tools can be used as both screening and identification or diagnostic measures. Although there are comprehensive assessment tools for communication, there are also domain-specific tools for language comprehension, receptive and expressive vocabulary, pragmatics, articulation, etc., which

Communication Assessment

Patricia Prelock

Communication Sciences and Disorders, Dean's Office, College of Nursing and Health Sciences, Burlington, VT, USA

Definition

Communication assessment is the evaluation of current skills in speech, language, syntax, semantics, morphology, and pragmatics. It is an important process for gathering information to answer questions and make intervention decisions (Schwartz et al. 2001). Importantly, too, the role of assessment extends beyond making diagnoses and identifying skill deficits. A comprehensive communication assessment helps pave the way for intervention planning.

As communication is often an area of difficulty for children with autism, communication assessment is essential in identifying and ultimately addressing the needs of these children to ensure

provide a more detailed examination of a particular area of language development that may be a specific area of challenge for a child with ASD.

Once a diagnosis has been made, the assessment process is not complete until the clinician can profile a child's communication strengths and challenges. Profiling the communication of a child with ASD allows the speech-language pathologist as well as the team, including the family, to develop a more holistic and comprehensive view of the child (Prelock 2006). Creating a communication profile is particularly important for prioritizing communication goals and implementing a developmentally and individually appropriate curriculum (Prelock 2006; Wetherby et al. 2000). Communication profiling requires the clinician to design situations which facilitate a child's ability to communicate and observing what a child does verbally and nonverbally in those situations. An assessment of joint attention is critical as is defining the various gestures, sounds, and words that characterize the child's repertoire (Prelock 2006). Specific assessment strategies are employed for those children with limited or absent verbal skills and those with unconventional verbal behavior. For verbal children and adolescents with ASD, a communication profile needs to carefully evaluate pragmatic language with several communication partners and across a variety of settings. Profiling pragmatic communication in more verbal children with ASD requires an assessment of communicative intent, use of presupposition, and social discourse.

Speech-language pathologists are primarily responsible for the assessment of communication and can provide activities within the home, school, and community to help facilitate communication development and monitor progress (Prelock et al. 2013).

To ensure that a child receives the full benefit of an intervention program, there must be a link between the comprehensive communication assessment (including a profile of communication strengths and challenges) that is completed and the communication goals and curriculum that are established for a child with ASD.

Definition

A communication board is a low-tech communication aid that is used in the field of augmentative and alternative communication (AAC). Typically, a grid with pictures on it is created, printed, and then affixed to something like a sturdy manila envelope. This type of assistive communication device is best for individuals with limited verbal output who are either preliterate or nonliterate. The communication board user will point to pictures to communicate wants and needs, to make comments, or to ask questions. See Beukelman and Mirenda (2012) for a detailed description of no- and low-tech communication devices and their implementation.

Communication Disorder/ Communication Impairment

Kailey MacNeill

Department of Communication Sciences and Disorders, The University of Vermont, Burlington, VT, USA

Synonyms

[Communication impairments](#)

Short Description or Definition

A communication disorder is a developmental or acquired impairment which generally affects language, speech, and/or hearing (National Institute on Deafness and Other Communication Disorders [NIDCD] 2010). The American Speech-Language-Hearing Association (ASHA) (1993) describes communication disorders more specifically, as impacting one's ability to "receive, send, process, and comprehend concepts or verbal, non-verbal and graphic symbol systems (p. 2)." These impairments may include, but are not limited to, problems with fluency, articulation, phonology, voice, auditory processing, pragmatics, syntax, semantics, morphology, and hearing loss (American Speech-Language and Hearing Association [ASHA] 2008; NIDCD 2010; Rochester Hearing and Speech Center [RHSC] 2011). Communication disorders generally fall on a continuum of severity, ranging from relatively mild to profound depending on the complexity of the impairment and which processes of communication are affected (ASHA 1993). Individuals may present with a single communication disorder or a

combination of various communication disorders. Depending on the nature of each individual’s impairment, a communication disorder may be a primary disability or it may be secondary to other disabilities (ASHA 1993). A communication disorder or impairment is one of the core deficits identified for individuals with an autism spectrum disorder (American Psychiatric Association 2000).

Categorization

Rather than being a disorder that can be categorized into a group with other like disorders, communication disorder is a category unto itself. Communication disorders include impairments associated with speech, language, and/or hearing, as outlined in Table 1.

Epidemiology

Given the complexity of communication disorders and the endless possibilities for presentations, it is difficult to identify a specific cause or origin. A wide variety of epidemiological studies have been conducted on the topic of communication disorders, and as the prevalence of related disorders increases, the interest in identifying the factors associated with such disorders continues to expand. Recent prevalence rates found that of the 6,068,802 children in the United States being served in public schools under the Individuals with Disabilities Act (IDEA), 1,460,583 (24.1%) are receiving services for speech and/or language disorders (ASHA 2008). It is important to consider that this statistic does not account for children receiving speech and/or language services

secondary to another disability such as autism spectrum disorders (ASD), children who do not qualify for services through the IDEA, for children who have not yet been identified, or children outside of the United States. As with many disorders and diseases, the number of individuals identified and diagnosed with communication disorders continues to grow with increasing knowledge, awareness, and skills of professionals and the general public.

It should be noted that for children to qualify for an autism diagnosis, they must exhibit a qualitative impairment in communication which may be manifested by one or more of the following: (1) delay in, or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gesture or mime); (2) in individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others; (3) stereotyped and repetitive use of language or idiosyncratic language; and/or (4) lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level (American Psychiatric Association 2000). Therefore, all children with autism will have communication disorders of varying degrees that affect their ability to understand, produce, and/or use communication in an effective and efficient manner.

Natural History, Prognostic Factors, and Outcomes

Identification of communication disorders in children can be especially complex, as symptoms, particularly those related to speech and language, do not typically present in the early months of life.

Communication Disorder/Communication Impairment, Table 1 Communication disorders

Speech	Language	Hearing
Articulation disorders	Receptive language disorder	Sensorineural hearing loss
Fluency disorders	Expressive language disorder	Conductive hearing loss
Voice disorders	Mixed receptive-expressive language disorder	Mixed hearing loss
	Specific language impairment	

ASHA (2008), NIDCD (2010), RHSC (2011)

Furthermore, disorder characteristics vary with each unique child (Ogletree et al. 2002). That being said, research has acknowledged factors that may play a role in determining prognosis, including family history of communication disorders or learning impairments, low socioeconomic status (SES), as well as familial hardships, such as single-parent households or parental substance abuse (Johnson et al. 2010). Further addressing issues of prognosis, research indicates that individuals who had early language impairments are more likely to experience unfavorable adult outcomes than those who had early speech impairments (Johnson et al. 2010).

Studies addressing outcome of communication disorders intervention have been mixed, in part due to the breadth of the topic. However, with improved identification and treatment techniques, therapy outcomes appear to be relatively positive, especially for those who were identified early and received intervention (ASHA 2008). While intervention for communication disorders often yields improvements, occasionally even complete remediation, it is essential to consider the additional confounding factors that may inhibit the treatment of individuals with conditions such as autism. Given that autism falls on a spectrum and each person experiences varying levels of cognitive, linguistic, social, and behavioral functioning, it is difficult to make a definitive statement regarding outcome (Howlin et al. 2004).

Clinical Expression and Pathophysiology

Communication disorder is an incredibly broad category, including multiple sub-disorders related to speech, language, and/or hearing. That being said, there are many clinical features that have been identified to facilitate early detection, diagnosis, and treatment (ASHA 2008; Diehl 2003; Drew et al. 2007). Speech disorders can be characterized by atypical articulation of speech sounds, impaired fluency of speech, as well as impaired voice production and/or quality (ASHA 2008). Language disorders can present in various forms but are typically known to affect the comprehension or use of an individual's language in

both verbal and written forms. Within the category of language disorders, individuals can experience difficulties with the form of language, including phonology, morphology, and syntax, the content of language, otherwise known as semantics, as well as the function of language, which is often referred to as pragmatics. Disorders associated with hearing include varying degrees of hearing loss, which can affect a person's ability to detect, comprehend, or discriminate the sounds of speech (ASHA 2008). As indicated above, communication disorders can present with any combination of impairments associated with speech, language, and/or hearing. In consideration of the various presentations of communication disorders as well as the importance of early identification and treatment, it is important for parents and caregivers who suspect a communication disorder to seek the guidance and support of a certified speech-language pathologist. Such a clinical professional can then determine if an evaluation and later treatment is warranted (ASHA 2008).

Evaluation and Differential Diagnosis

As with most disorders, early and accurate identification and diagnosis are essential components in effective intervention of communication disorders. Furthermore, since children with autism have difficulties with one or multiple components of communication, early assessment of communication skills is often necessary to appropriately address the needs of these children and ensure future communicative success. The goal of communication assessment is to evaluate a child's current level of communicative skills across various settings and with different partners (Ogletree et al. 2002). Assessments utilized in the evaluation process can be standardized or non-standardized tools. Standardized measures, often in the form of tests, require, as the name implies, standard administration and scoring to ensure consistent and accurate interpretation of results. Non-standardized measures, such as observations and caregiver interviews, as well as some tests, allows a clinician to obtain information in a flexible and sometimes more functional manner.

Ideally, both standardized and non-standardized data are obtained throughout the assessment process and can be used to plan the most effective and functional course of treatment, given each individual's needs and abilities (Ogletree et al.; Wetherby and Prizant 1999). There are a great deal of components considered in the evaluation process that allow for identification of disorders as well as differential diagnosis. Some components of communication that are often assessed are ability to engage, attention skills, nonverbal behaviors, and gestures, as well as form, content, and use of speech and language.

Treatment

Equally as significant as early identification, early intervention is an important consideration when addressing communication skills. Accounting for the individualized presentation of each child with autism and given the varying levels of skills and abilities, communication intervention should be based on information obtained throughout the assessment process (Ogletree et al. 2002). Communication intervention often seeks to improve skills associated with the form, function, and content of the communicative act, as well as engagement and attention skills, nonverbal behaviors, and gestures (Paul 2008). As communication skills fall on a continuum, there are a plethora of different intervention approaches available. Generally, clinicians should choose an intervention method which is supported with evidence-based research while also fulfilling the personal and clinical needs of the child and their family. Such approaches range from behavioral techniques, which target the functional and social behaviors related to communication, to augmentative and alternative communication aids, which utilize both high- and low-tech aids to facilitate communication (Diehl 2003; Paul 2008).

Communication Intention Inventory

Sarita Austin
Unlocking Language, London, UK

Synonyms

[CII](#)

Description

The *communicative intention inventory* (CII) is an observational system for recording children's early intentional communication, including gestural, vocal, and verbal communicative behaviors, while the child is engaged in a free-play situation with a caregiver.

The CII is designed to support the clinician in observing and coding the intentional communication of children functioning at the 8 to 24-month developmental level. Intentional communication is defined as a child's goal-oriented, purposeful reasons for vocalizing, gesturing, and speaking. Often, particularly in

the preverbal period, children's intentions must be deduced by their behaviors in relation to objects and people. It is these preverbal intentions, and their expression in the use and coordination of gestures, vocalization, and gaze, that serve as the communicative foundation for the emergence of language.

Historical Background

When Drs. Truman Coggins and Robert Carpenter of the University of Washington first introduced the *communicative intention inventory* (CII) in 1981, the assessments available for describing child's communicative intent were limited. The existing measures at that time included a small number of intentional categories used for describing children's behaviors, inadequately described the categories presented, and provided no information to support the reliability of the categories. The authors therefore attempted to develop the CII with good content and construct validity (i.e., with categories that are believed to adequately reflect instances of early intentional communication and the range of communicative functions involved in it).

The *eight intentional categories* included in the CII are:

1. Comment on action
2. Comment on object
3. Request for action
4. Request for object
5. Request for information
6. Answering a request for information
7. Acknowledging that a previous gesture or utterance was received
8. Protesting

Administration

The authors suggest that the free-play session with child and caregiver should be videotaped through a two-way mirror and monitored in a control room by an individual familiar with the CII. Although this is a criterion-referenced measure, the authors indicated that the recording should be approximately 45 minutes in length if the clinician

would like to do comparisons against the preliminary data they reported for the measure. Stimulus materials should include a variety of toys and books that allow the child to create a variety of activities. No other distracting material should be in the assessment room, and only the child and caregiver should be present during the recording. A familiar caregiver is believed to support obtaining a representative sample of the child's communicative functioning regardless of the familiarity of the testing environment. A written script is included to be read to the caregiver prior to beginning the recording. The purpose of the script is to inform the caregiver of the reason for recording the session and to encourage them to follow the child's lead while refraining from interacting minimally or asking too many questions.

Scoring

The authors of the CII suggest that the video be scored as soon as possible and ideally by the person who monitored the recording. A training procedure for all scorers is also outlined to minimize variability in scorer coding. Only intentionally communicative behaviors are to be coded. Therefore, all coded behaviors must occur in a shared or joint activity. Criteria for what constitutes a joint activity are also described. Each instance of an intentionally communicative behavior is assigned to a single category and given a score of 1. Only those behaviors that fit into one of the CII's eight intentional categories can be scored. Specifics on how to handle repetitions of gestures, vocalizations, and verbalizations are also addressed.

Psychometric Data

The *communicative intention inventory* (CII) was designed as a criterion-referenced measure of the intentional communication of a child and thus compares each child's performance in comparison to a standard or objective, rather than a normative sample. The eight intentional categories included were selected based on their content and construct validity. The CII includes

categories that are believed to adequately reflect instances of early intentional communication and the range of communicative functions involved in it based on the existing literature in early intentional communication. The categories included are believed to be necessary for the acquisition of future conversational discourse skills.

The reported internal test reliability was 0.66, based on a sample of 16 monolingual, native English-speaking typically developing children between 15 and 16 months of age in Piaget's sensorimotor stage V. The authors believe the score was affected by the homogeneity of the participants. Percentile ranks and standard deviation scores were also provided for frequency of demonstration of each of the eight intentional categories in the same sample group.

In terms of inter-scorer reliability, 10 graduate students in speech-language pathology programs (who underwent CII's outlined scorer training procedure and independently scored a recording of 33 behavioral sequences) received a mean proportion of correct coding of behavioral sequences score of 91. All judges also coded all four behavioral sequences that did not demonstrate communicative intent as "unscorable."

Content validity was established based on the creation of the inventory format and behavioral definitions founded on existing early communicative development research studies, language acquisition literature, and the authors' observations of parent-child interactions. When this measure was initially published in 1981, specific studies were not undertaken to establish construct validity though the authors believed that indirect evidence (i.e., the existing literature on social development in children with autism spectrum disorder, the literature on onset of intentionality in children with typical development, and hypotheses regarding children's performance on the CII) supports the CII's utility for assessing intentional communication behaviors. The authors published a study 2 years later noting no significant difference in the performance of children with Down syndrome and children with typical development on the CII.

Clinical Uses

The *communicative intention inventory* (CII) allows the clinician to describe a child's early communicative behaviors across eight intentional categories. Communicative intent is believed to form the basis of later social interaction, making the CII a potentially useful tool in determining intervention goals and predicting future social functioning based on a child's performance on the measure. The CII was specifically designed to observe and code the intentional communication of children functioning between Piaget's sensorimotor stages IV and VI. As research in language acquisition supports the idea that nonverbal expression of early communicative intentions precede and may support the development of future conversational skills, the authors suggest that the CII might also be useful with nonverbal children with and without cognitive delays both as an initial assessment tool and a measure of response to therapy.

These eight intentional behaviors (i.e., comment on action, comment on object, request for action, request for object, request for information, answering, acknowledging, and protesting) were selected based on their frequency of use among children in the sensorimotor stage, their likelihood to occur in a clinical setting, and the ability to develop an operational definition for them. Within each intentional category, descriptions of some expected behaviors are presented within subcategories (i.e., "gesture or gestural/vocal" and "verbal") to indicate how the intention was coded. For example, for the *Comment on Object* category, "points to, looks toward, or approaches entity may vocalize" (gestural or gestural/vocal) and "extends arm to show entity in hand and produces a word" (verbal) are both included as specific behaviors that a child may exhibit. General descriptions of the criteria for inclusion within the subcategories of "gesture or gestural/vocal" and "verbal," and samples of parent-child interactions for classification practice are also provided.

The CII allows the clinician to determine which of the eight intentional categories are present and the manner (i.e., gestural, vocal,

or verbal) in which they are expressed in order to determine if a child's language difficulties are specifically associated with their ability to use language effectively. The authors suggest that further analysis may be done regarding other aspects of language, such as productivity, by applying information from existing language acquisition literature. The authors remind the clinician that the percentile ranks and standard deviations reported for the 16 children with typically development are not intended to be used as referenced norms but are simply provided to describe the behavior patterns in that particular group and aid the clinician's interpretations.

Communication Intentions

► Communicative Functions

Communication Interventions

Patricia Prelock

Communication Sciences and Disorders, Dean's Office, College of Nursing and Health Sciences, Burlington, VT, USA

Definition

Early identification and intervention are key factors when addressing communication skills. Upon completion of a comprehensive communication assessment, it is important to address any communication deficits identified. As each child with autism presents with varying levels of skills and abilities, communication intervention should be based on individualized information obtained throughout the assessment process. Communication intervention should focus on improving skills associated with the form, function, and content of the communicative act, as well as increasing engagement and attention skills, nonverbal behaviors, and gestures. Given that communication skills often fall on a continuum, there are a variety of different intervention approaches available, each of which originates from one of many philosophies. Such philosophies range from behavioral techniques that target the functional and social behaviors related to communication to augmentative and alternative communication aids, which utilize both high- and low-tech aids to supplement communication, to naturalistic approaches that seek to foster communication in the natural environment, including home, school, the job setting, and community-based activities.

Children's language and communication abilities are best facilitated through the relationships they establish with family members and their interventionists as well as a result of environmental changes and communication partner development (Prelock 2006). It is important that communication interventions address the core deficits that characterize children with autism spectrum disorders (ASD), including those that can facilitate communication in play and social interaction.

Notably, many communication intervention strategies are rooted in behavioral principles and strategies such as prompting, modeling, and reinforcement (Brown and Murray 2002). Most speech-language pathologists, however, employ social-pragmatic developmental approaches to address the primary social-pragmatic deficits that characterize children with ASD.

Because communication is such a critical skill for learning and connecting with others, children with ASD who have minimal verbal skills are often limited in their ability to participate in play and socialize with adults or peers (Prelock 2006). As a result, some children engage in less conventional ways to communicate their intent, often substituting undesirable behaviors to communicate their needs. Speech-language pathologists have a critical role in addressing the communication needs of children with ASD who exhibit limited verbal abilities. Some of the intervention approaches they might select include but are not limited to joint action routines, minimal speech approach, proximal communication, prelinguistic milieu teaching, augmentative communication, functional communication training, visual supports, parent training, More Than Words™, and the Picture Exchange Communication System™.

As children with ASD begin to develop their oral communication and can communicate verbally, they are likely to require additional support to use their verbal communication skills in the most effective manner to learn and interact across a variety of contexts and with various communication partners. For children with ASD who are verbal, speech-language pathologists might employ interventions such as enhanced milieu teaching, time delay, pivotal response training, modeling, video modeling and video self-modeling, scripting, Talkability™, Social Stories™, and comic strip conversations (Prelock 2006).

Importantly, communication interventions for children with ASD can be used to help manage unconventional verbal behaviors as well as challenging behaviors since behavior is often a child's attempt to communicate. Although not directly related to communication interventions, approximately 52 % of parents of children with ASD have used at least one complementary and

alternative medical (CAM) therapy with their child with ASD to address behavioral and communication challenges (Wong and Smith 2006). Most of the interventions families select are biologically based (e.g., special diets or supplements), and at least 75 % felt the therapies were beneficial (Wong and Smith 2006). CAM interventions, however, have not been widely investigated as a strategy to support communication in children with ASD.

The selection of any communication intervention must consider the context, the available evidence, the child's relative communication strengths and challenges, and the child's communication goals (Prelock and McCauley 2012). Several intervention reviews guide clinicians and families in their pursuit of the most appropriate intervention approaches (for more information, see reports from the Agency for Healthcare Research and Quality 2014; National Autism Center 2009, 2015; Stansberry-Brusnahan and Collet-Klinenberg 2010; Wong et al. 2014).

Communicative Acquisition in ASD

Rhiannon J. Luyster

Department of Communication Sciences and Disorders, Emerson College, Boston, MA, USA

Short Description or Definition

The development of communicative skills begins in the earliest months of life. Communication can be conceived as any action that conveys information to establish a shared understanding with another individual. It is comprised of a complex set of skills, including language, as well as a number of nonverbal behaviors like gestures, facial expressions, and body posture. Communication – whether verbally or nonverbally expressed – has long been understood to be an area of core impairment in ASD, and research has uncovered deficits in communication development within the first year of life for children who go on to develop ASD. These difficulties are usually persistent, continuing to affect both verbal and nonverbal aspects of communication throughout the lifespan.

Natural History, Prognostic Factors, and Outcomes

Prior to the development of language, typically developing infants make a number of communicative achievements starting only months after birth. They attend preferentially to their caregivers' face (Bushnell 2001) and speech (DeCasper and Fifer 1980), and by 3 months of age, infants smile reciprocally (Emde et al. 1976). By the end of the first year, they produce early speech sounds and perhaps even single words, use gestures to direct others' attention, and follow social cues conveyed in movements and gaze (Fenson et al. 1994).

In contrast, children who are later diagnosed with ASD show broad deficits in early communication. Within the first year of life, children with ASD show reduced social smiling and reciprocal engagement with partners (Zwaigenbaum et al. 2005). Unlike typically developing toddlers, young children with ASD do not preferentially attend to child-directed speech (Kuhl et al. 2005; Paul et al. 2007), instead preferring to listen to nonspeech analog signal. They show delays and deficits in the emergence of early gestures, joint attention, and imitation (Mitchell et al. 2006; Shumway and Wetherby 2009; Wetherby et al. 2007). These skills are all critical developmental precursors to language, and deficits in these non-verbal abilities are associated with deficits in verbal competence (Luyster et al. 2008).

One of the earliest forms of vocal communication in infants is crying, and infants who go on to receive an early ASD diagnosis have cries that are qualitatively different than controls, showing more dysphonation and less modulation (Esposito and Venuti 2009). When the first speech sounds emerge for young children, they are in the form of canonical babbling. In infants and toddlers later identified with ASD, these sounds may have unusual vocal qualities (Schoen et al. 2011; Sheinkopf et al. 2000) or have a restricted consonant range (Wetherby et al. 2004). By around 1 year of age, children with ASD are already falling behind their unaffected peers in receptive and expressive language development, showing delays in the attainment of first words (Landa and Garrett-Mayer 2006; Mitchell et al. 2006; Zwaigenbaum et al. 2005). Receptive language skills are particularly impaired starting in the first few years of life (Hudry et al. 2010; Weismer et al. 2010) and continuing into childhood.

The process of learning words is driven, at least in part, by social engagement and attention (Baldwin et al. 2011; Baldwin and Moses 2001; Tomasello and Barton 1994). Longitudinal studies have suggested that slowed development in language – especially receptive – for children with ASD is partly a product of their overall difficulty with social engagement (Bopp et al.

2009). Indeed, the aforementioned tendency of children with ASD to direct their attention more toward nonspeech sounds than to child-directed speech is associated with lower expressive language development (Kuhl et al. 2005). Similarly, children with ASD who showed greater physiological responsiveness to child-directed speech at an initial evaluation exhibited better communication skills 1 year later (Watson et al. 2010), pointing to a critical link between social attention and communicative development.

The question of how children with ASD, who experience deficits in attending to social input, learn new words has been addressed in a variety of studies. Results generally suggest that children who are able to attend to the social cues of others are able to use those cues to learn new words (Franken et al. 2010; Luyster and Lord 2009; Parish-Morris et al. 2007); the children who experience more profound deficits in social attention may not be able to successfully extract these cues for the purpose of language learning (Baron-Cohen et al. 1997; Preissler and Carey 2005). The importance of relatedness with social partners for language development has also been reported by studies finding an association between parental responsiveness to child interest and child language (McDuffie and Yoder 2010; Siller and Sigman 2008).

A number of other cognitive biases have been proposed as important mechanisms for learning language, including the “noun bias” (by which children map a novel word onto an unknown object rather than an action or feature) and the “shape bias” (which supports children in generalizing words based on similarity of shape). Young children with ASD seem to abide by the former, accurately mapping new words onto objects rather than some other aspect of the visual scene (Swensen et al. 2007). However, they are less adept at following the shape bias, failing to extend terms to same-shaped objects (Tek et al. 2008).

Patterns of change over time in communication development have been a focus of recent research. In general, children with ASD show improvement in language and communication with age

(Ballaban-Gil et al. 1996; Lord et al. 2004a; Paul et al. 2008). However, a minority of children may experience a period of loss early in life. This phenomenon – called “regression” – has been reported in several retrospective and early home video studies (Baird et al. 2008; Hansen et al. 2008; Lord et al. 2004b; Werner and Dawson 2005). The initial portrait of this developmental shift was a sudden-onset loss that primarily affected language skills and occurred around the second birthday. Conceptualizations have gradually broadened to reflect the wider range of social communication skills that seemed to be affected, including reciprocal engagement, social attention, and shared enjoyment (Baird et al. 2008; Luyster et al. 2005). Interestingly, prospective studies have also uncovered evidence for loss of skills, but the characterization of this shift is somewhat different from the retrospective and video review reports. Ozonoff and colleagues noted a gradual deterioration in social communication skills between 6 and 18 months of age (2010), and a similar pattern has been observed elsewhere (Bryson et al. 2007).

The understanding and use of language require the mastery of a complex set of sounds and rules, and individuals with ASD have been found to experience difficulties at nearly every level of language development. It is important to note that, although all individuals with ASD (by definition) experience some sort of impairment in language and communication, any specific area of difficulty is not universal to the conditions. Despite these difficulties, more than two-thirds of individuals with ASD eventually acquire spoken language (Anderson et al. 2007; Turner et al. 2006) though it can range from single words to complex, fluent speech. Early emergence of language (particularly by age 3) is a positive predictor of a number of outcomes (Ben Itzhak and Zachor 2009; Charman et al. 2005). It is associated both concurrently and longitudinally with a variety of skills including joint attention (Adamson et al. 2009; Dawson et al. 2004; Sigman and McGovern 2005), gesture use (Ingersoll and Lalonde 2010; Luyster et al. 2008; Smith et al. 2007), play (Mundy et al. 1987; Sigman and McGovern 2005), imitation

(Carpenter et al. 2002; Charman et al. 2003; Stone et al. 1997), and cognitive skills (Luyster et al. 2008; Thurm et al. 2007). Furthermore, the strength of early verbal skills is positively associated with response to treatment in young children with ASD (Ben Itzhak and Zachor 2011).

Clinical Expression and Pathophysiology

When language is acquired, it is often atypical in a variety of ways. Indeed, some of the first written accounts of the disorder included observations of odd speech patterns (Kanner 1943, 1946). Individuals with ASD may use language without apparent meaning; for instance, they may repeat previously heard words or phrases (termed “echolalia”). This behavior can occur immediately after the child hears a word or phrase, or it may be delayed by several hours or days. The former – “immediate echolalia” – appears to be more common in individuals with limited language (McEvoy et al. 1988). More advanced language users may incorporate chunks of speech heard previously into their speech in a scripted fashion (Nadig et al. 2010). Examples of this could include a phrase spoken by the parent earlier in the day (e.g., “It’s snowing cats and dogs!”) or the introductory sequence to the *Powerpuff Girls* television show. Other individuals may make up words that do not have any conventional meaning (termed “neologisms”) (Volden and Lord 1991). For instance, a child might call all cups “tamots” or referring to anything with stripes as “surry.” In individuals with more advanced language, speech can be idiosyncratic, characterized by overly formal use of words or unusual formation of sentences (Nadig et al. 2010; Paul et al. 2009). For instance, rather than simply saying, “I like reading books,” the individual might use more pedantic phrasing like, “I enjoy engaging in literary endeavors.” Idiosyncratic phrasing could include asking, “How many years are you?” instead of “How old are you?” or referring to rainbows as “color bows.”

There have been some deficits reported in vocabulary acquisition and use, although results are not consistent. On the one hand, vocabulary

knowledge across general categories (e.g., modifiers, nouns, predicates) seems to be indistinguishable from typically developing controls (Charman et al. 2003; Luyster et al. 2007). However, usage of some specific vocabulary types – such as mental state terms (Tager-Flusberg 1992), social-emotional identifiers (Hobson and Lee 1989), or deictic terms (Hobson et al. 2010) – may be impaired in an individual with ASD. An example of this is pronoun reversal, such that the individual uses the term “you” instead of “I” or “me” or refers to himself or herself in the third person (Lee et al. 1994).

The degree to which semantic and lexical organization is disrupted remains unclear. Children with ASD do well on standardized vocabulary tests (Kjelgaard and Tager-Flusberg 2001) and generalize terms in a usual manner. Some studies have reported that individuals with ASD form conceptual categories in a similar fashion to their typically developing peers (Tager-Flusberg 1985), while others reported differences in the connectedness of conceptual and lexical knowledge (Dunn et al. 1996). One possible explanation to this apparent discrepancy is the suggestion that impairment may be specific to certain kinds of conceptual categories (e.g., animate beings; Kelley et al. 2006).

In general, grammar and syntax seem to follow a typical path of development (Tager-Flusberg et al. 1990; Waterhouse and Fein 1982). However, there is some indication that the range of grammatical constructions spontaneously used by individuals with ASD may be limited. Other difficulties have been noted, including morpheme omission and failure to correctly mark tense (Bartolucci et al. 1980; Eigsti and Bennetto 2009; Roberts et al. 2004).

The area of language and communication that is most universally disturbed is pragmatics, or the social use of language. For example, individuals with ASD may use language in restricted ways. That is, whereas language is broadly used for a variety of purposes (making requests, as well as sharing information, conveying interest, or directing attention), individuals with ASD may employ language predominantly to express their own needs, wants, or interests and only minimally

for purely social purposes (Loveland et al. 1988; Wetherby et al. 2007). As a result, maintaining reciprocal conversations is often quite difficult for individuals on the autism spectrum, who experience impairments in turn-taking and using socially appropriate questions and statements (Capps et al. 1998; Loukusa et al. 2007; Paul et al. 2009) (Jones and Schwartz 2009). Difficulty maintaining back-and-forth dialogue may also present as rigidity in language use, sometimes referred to as “verbal rituals.” This pattern of behavior is characterized by a need for a language to follow a certain predictable routine rather than flow naturally. This can consist of a compulsive sequence of utterances spoken by the child – an example might be the need to recite book titles in alphabetical order without interruption – or it could be the desire for an interchange to abide by a particular routine. For instance, the child might have a habit of saying, “Welcome boys and girls! The color of the day is. . .” and insist that the parent answer, “The color of the day is red!” to which the child responds, “And after red is. . .” and expects the parent to answer “After red is orange!” and so on through a series of colors. Any disruption of this specific pattern and phrasing is often distressing for the child, with the focus being on the need for language predictability rather than social usage.

The understanding and use of nonlinguistic communicative cues, such as prosody, gestures, facial expressions, and gaze, commonly present a challenge to individuals with ASD. Understanding and using language that hinges on these nonlinguistic cues (such as humor or irony) are often impaired (MacKay and Shaw 2004; Rundblad and Annaz 2010; Wang et al. 2006) as is the use of a range of nonverbal cues. For instance, the speech of individuals with ASD may sound robotic or monotone; in other cases, it may have exaggerated ups and downs (Paul et al. 2005; Peppé et al. 2011; Shriberg et al. 2001). Vocal atypicalities carry over from speech into laughter, which is restricted in range and variety relative to controls, suggesting that individuals with ASD may not modulate their laughter for different communicative purposes (Hudenko et al. 2009). Difficulties with expressive prosody are accompanied by

deficits in accurately interpreting the significance of others' prosodic cues (Korpilahti et al. 2007; Rutherford et al. 2002).

Individuals with ASD show decreased use of gestures, facial expressions, and gaze in communicative situations whether with or without language use (Garcia-Pérez et al. 2007; Lord et al. 2000; Loveland et al. 1988). Similarly, whereas the perception of gestures facilitates language comprehension for typically developing individuals, individuals with ASD experience a detriment in speech comprehension when the speaker uses concurrent gestures (Silverman et al. 2010), indicating that verbal and nonverbal cues may not be processed as complementary pieces of a unified communicative message.

These observable abnormalities of communication and language are accompanied by atypical structural characteristics of associated brain regions. Volumetric differences in areas underlying social and emotion processing are associated with social communication impairments on behavioral measures (Kim et al. 2011; Mosconi et al. 2009; Parks et al. 2009; Schumann et al. 2009). Similarly, structural differences have emerged in brain regions known to be associated with language processing (McAlonan et al. 2005; Rojas et al. 2006), and some of these structural differences are associated with variability in language for children with ASD (De Fossé et al. 2004; Knaus et al. 2009).

Functional investigations have yielded very promising findings as well. Differences in activation have been noted in regions serving non-linguistic communicative cues, including the amygdala, left temporal lobe, and prefrontal cortex (Critchley et al. 2000; Hesling et al. 2010; Wang et al. 2007). In the case of typical development, language processing is lateralized, occurring predominantly in the left cerebral hemisphere. However, a number of studies have indicated that language processing in individuals with ASD does not follow this pattern. A lack of left hemisphere lateralization has been reported, with profiles of either bilateral or right hemisphere activation being observed instead (Flagg et al. 2005; Kleinhans et al. 2008; Minagawa-Kawai et al. 2009) starting from very early on in life

(Redcay and Courchesne 2008). There seem to be behavioral correlates of these neural differences in that reduced asymmetry is associated with greater language impairment for individuals with ASD (De Fossé et al. 2004; Herbert et al. 2005).

The centrality of communication, whether verbal or nonverbal, to our understanding of ASD ensures that it will remain a primary focus of research and clinical endeavors in the years to come. Strides continue to be made in standardizing definitions and measures (Tager-Flusberg et al. 2010), an important step in unifying efforts and optimizing the applicability of research findings to applied settings.

Description

2nd Edition CDIs (2007)

The MacArthur-Bates Communicative Development Inventories (CDIs) are standardized, norm-referenced, parent-report measures of early language and communication. All reference here pertains to the 2nd edition English-language publication (Fenson et al. 2007), unless otherwise stated. A User's Guide and Technical Manual (hereafter, Manual) accompanies three alternative test forms: CDI-Words and Gestures (CDI-WG), CDI-Words and Sentences (CDI-WS), and CDI-III. The 2nd edition Manual (Fenson et al. 2007) updates and expands upon its predecessor (Fenson et al. 1992), providing details around:

Theoretical rationale for the CDIs

History of development of the CDIs

The various sections and items on each test form

Administration and scoring of the forms and interpretation based on normative data
Clinical and research uses of the CDIs

The Manual Appendix includes some photocopyable forms which (a) facilitate the summary of an individual's CDI scores and (b) guide the types of background data which might be sought concurrently.

CDI-Words and Gestures. With a normative sample of 1,089 infants aged 8–18 months, the CDI-WG evaluates early comprehension and production of language and nonverbal communication. Several subsections are arranged within two major parts. Part 1 evaluates infants' *First Signs of Understanding*, including whether they have begun to respond to language (e.g., recognizing own name) and whether they understand commonly used phrases (e.g., "give it to mommy"). Parents then report on infants' *Starting to Talk* (i.e., word/phrase imitation and early object labeling). The *Vocabulary Checklist* presents 396 words within 19 semantic categories (e.g., animal names, toys, etc.), and parents indicate those words their infant "understands" and "understands and says." Raw expressive vocabulary (i.e., all "understands and says") and receptive vocabulary (i.e., all "understands" or "understands and says") can be totaled.

Part 2 evaluates 63 communicative and symbolic *Actions and Gestures*, presented within five categories. *Early Gestures* include *First Communicative Gestures* (e.g., pointing and showing) and *Games and Routines*, signaling emerging intentional communication and social engagement. *Later Gestures* include *Actions with Objects*, *Imitating other Adult Actions*, and *Pretending to be a Parent*, signaling the developing awareness of objects' functional and representational uses.

CDI-Words and Sentences. With a normative sample of 1,461 toddlers aged 16–30 months, the CDI-WS evaluates later aspects of language production, including expressive vocabulary, grammar, and syntax. Several subsections are again arranged within two parts. Part 1 evaluates *Words Children Use*, presenting a *Vocabulary Checklist* of 680 words arranged within

22 categories. Parents indicate those words their toddler "understands and says," providing an expressive (but not receptive) vocabulary count. *How Children Use Words* considers reference to the past and future, etc. Part 2 evaluates *Sentences and Grammar*, including *Word Endings* (i.e., regular plurals, possessive forms, etc.), and *Word Forms/Endings* (i.e., irregular nouns/verbs, and over-regularizations). Within *Word Combinations*, parents indicate whether their toddler at all combines words, and if so, they transcribe the three longest phrases/sentences recently produced. From these, the *Mean length of Three Longest sentences* (M3L; see Manual, pp. 22–23) is computed (akin to Mean Length of Utterance [MLU]). Finally, parents report on their toddler's current level of *Complexity*, indicating which exemplar within each of 37 pairs of phrases best matches the toddler's current speech (e.g., "that my truck" vs. "that's my truck").

CDI-III. A new addition, the relatively short CDI-III, was designed as an upward extension of the CDI-WS, using a normative sample of 356 children aged 30–37 months. Expressive vocabulary is assessed with a 100-item *Vocabulary Checklist* (around half of items overlap with CDI-WS items). Sentence *Complexity* is assessed using 12 sentence pairs, and *Language Use* questions (not included in the CDI-WS) assess aspects of comprehension, semantics, and syntax. Pilot testing informed the retention of some appropriate items from the CDI-WS and the inclusion of other new items, and the upper age limit of 37 months was adopted given the substantive ceiling scores observed beyond this age.

Spanish CDIs

While numerous other-language CDI adaptations are currently underway (see section "Other Language Adaptations"), two Spanish version CDIs have progressed to the level of Manual publication. The Spanish (Mexican) version comprises a full-test pack, including a Users' Guide and Technical Manual (Jackson-Maldonado et al. 2003), and accompanying CDI-WG and CDI-WS forms. A Spanish (European) version (Lopez Ornat et al. 2005) has been adapted from the former.

Additional Developments

CDI Short Forms

Brief CDI-WG and CDI-WS forms (Fenson et al. 2000) are mentioned within the 2nd edition Manual (Fenson et al. 2007, pp. 13–14), but not published alongside it. These are purchased directly from the authors (refer to *See Also*) and present a subset of the appropriate *Vocabulary Checklist* items. Level 1 maps on to the CDI-WG for 8–18-month-olds, and two (alternate version) level 2 Short Forms map on to the CDI-WS for 16–30-month-olds. Each form also enquires about whether the child yet combines words. Completion time is around 10 min, permitting rapid assessment of vocabulary acquisition, and interview administration format can be used if needed (e.g., in cases of low parent literacy), although normative data were collected using the standard checklist format.

Other Language Adaptations

A CDI Advisory Board promotes (and authorizes) adaptation of the CDIs for other non-English languages, some accompanied by normative data and all available for public use. Section “See Also” contains more information, as does the Advisory Board website: <http://www.sci.sdsu.edu/cdi/>

Historical Background

Interest in language development has a long history, and the current CDIs have evolved over 30 years (Fenson et al. 2007). Parent reports have regularly informed child language and communicative assessment, with diary studies common early on. Into the 1970s and 1980s, research programs led by Elizabeth Bates and Leslie Rescorla endeavored to develop more user-friendly questionnaire formats for parent report. Precursors to the current CDIs were four earlier questionnaires; the Communicative Development Questionnaire (8–12 months), Language and Gesture Inventory (12–18 months), Early Language Inventory (18–24 months), and Grammatical Development Questionnaire (24–36 months). The 1st edition CDI Manual, CDI-WG, and

CDI-WS forms were published in 1992 (Fenson et al. 1992), with Italian versions also developed and published around this same time (Caselli and Casadio 1995). A research monograph on early communication development also appeared in 1994, presenting detailed analysis of data from the English-language normative sample. This included developmental trajectories of the various CDI skills, and evaluation of the correspondence across skills domains, and consideration of the impact of factors such as gender, birth order, and social class on language development (Fenson et al. 1994).

The CDI Manual is currently in its 2nd edition (Fenson et al. 2007). While the inventory forms have seen no substantive alteration, updates to the Manual include an improved normative data set, brief presentation of the Short Forms, and introduction of the CDI-III. Instructions for administering, scoring, and interpreting the CDIs were also expanded upon, and more details were included on the instrument psychometric properties and on research and clinical application. As undertaken with the original normative sample (Fenson et al. 1992, 1994), the updated Manual also includes analysis of developmental trajectories and cross-domain correspondence, along with some evaluation of the impact of other factors on language acquisition/development (Fenson et al. 2007; see section “Psychometric Data”).

Psychometric Data

Normative Samples

Normative data for the CDIs have been collected in two phases. During initial instrument development, 659 CDI-WG forms and 1,130 CDI-WS forms were completed (Fenson et al. 1992). In preparing the 2nd edition Manual (Fenson et al. 2007), an additional 430 CDI-WG and 331 CDI-WS forms were collected. The authors sought to increase the CDI-WG normative range up to 18 months, rather than just 16 months (as in the 1st edition). Increased sample diversity was also sought, to better align with US census records around ethnicity and parent educational level. Ethnic distribution of the 2nd edition normative

sample does better match US census records, albeit with fewer Hispanic respondents than expected, likely due to the inclusion criterion of English as the primary home language, for this sample. Parental education levels remain above the US average, although good variability is included within the 2nd edition normative sample: around 30% of respondents held a high-school diploma or lower level of completed education (Fenson et al. 2007). Geographical sampling (across US states) was also improved for the 2nd edition.

Reliability

The Manual reports reliability in terms of internal consistency (IC) and test-retest reliability (TRT) across the broad skills domains assessed within the CDI-WG and CDI-WS forms (Fenson et al. 2007, pp. 99–102). These various *Vocabulary Checklist* components (CDI-WG comprehension and production and CDI-WS production) all evidence very strong IC, as do the CDI-WS sentence *Complexity* items. IC is lower, however, for CDI-WG *Gestures* items: while the *Actions with Objects* and *Imitating Other Adult Actions* correlate quite highly together, those among the other three sections are lower. TRT reliability is assessed across a maximum inter-assessment interval of 2 months, within a subgroup of the normative sample. CDI-WS expressive vocabulary counts for 216 toddlers were very stable. CDI-WG receptive vocabulary counts and gesture scores were similarly stable for 137 infants, with the single exception of those aged 12 months at initial assessment (see Fenson et al. 2007, p. 101 for discussion). CDI-WG expressive counts were also quite stable, except for infants aged 8–10 months at initial assessment (and likely due to floor effects at these young ages; Fenson et al.).

The authors acknowledge difficulties inherent in assessing the reliability of a parent-report instrument, including the possibility for halo effects and recall bias to impact upon IC and TRT reliability estimates. Ideally, evaluation of inter-rater reliability (IRR) would also be included, but this requires availability of a second respondent, equally familiar with the child's

abilities (frequently improbable). The authors argue, however, that strong evidence of validity (see below) presupposes robust reliability, further strengthening the case for reliability of the inventories (Fenson et al. 2007).

Validity

The Manual reports on face, content, convergent, concurrent, and predictive forms of validity across the broad skills domains assessed within the CDI-WG and CDI-WS (Fenson et al. 2007, pp. 102–114). Face validity is supported by the professional appearance of the checklist forms, along with the breadth and depth with which language and communication skills are addressed in the assessment. The authors feel that parents will consider the CDIs as valid and comprehensive assessments of their children's abilities and thereby provide considered responses. Content validity is evidenced in the authors' use of the language development literature to ensure inclusion of those aspects of early language and communication development most important at the ages assessed. While phonology and communicative pragmatics fail to be represented in the CDIs, the authors maintain that those aspects included are given comprehensive coverage (Fenson et al. 2007).

Convergent validity is evidenced from the observation of correlations between CDI scores and language/communication data obtained through other methods (see Fenson et al. 2007, Chap. 4, and Fenson et al. 1994, for details). In brief, developmental trajectories across various broad communication and language domains evaluated in the CDIs are shown to increase consistently and regularly across ages assessed. Each skill domain assessed demonstrates an onset around the age at which it would be expected (given the broader literature), and rates of development correspond similarly to expectations from past research. Individual variability similarly corresponds to that which would be expected. Fenson et al. (2007) note some clear exceptions, however, including the parents of some 8-month-olds reporting greater receptive vocabularies, and other parents reporting much earlier onset of

some pretense skills, than would be expected (see Manual, p. 103). On the whole, however, evidence for convergent validity is substantial. Fenson et al. (2007) argue that parents and researchers appear to be observing and reporting upon the same development phenomena irrespective of the research method employed (i.e., CDI report vs. laboratory experiment).

Evidence for concurrent validity emerges through the comparison of results from one test (i.e., parts of a CDI form) with those arising from other similar assessments (e.g., formal language tests, naturalistic language samples, etc.). A measure's evaluated concurrent validity is influenced not only by its own indices of reliability and construct validity but also by those of the comparison measure. Furthermore, strong concurrent validity will only be evidenced when the target and comparison measures assess an *equivalent* skill, a potential problem for the CDIs. Parent reports of child language draw on a wealth of knowledge about the child and daily exposure to his/her communication and are sought for the very reason that they are unlikely to correspond perfectly language skills assessed using other means (e.g., during a formal one-off test with an unfamiliar adult, or during a relatively brief naturalistic language sample, Fenson et al. 2007). Notwithstanding, *Vocabulary Checklist* counts show moderate-to-strong correspondence with other vocabulary and language measures (see a tabulation of various study results in Fenson et al. 2007, pp. 106–107). More limited, however, is the evidence around *Gestures*, given the dearth of other accepted measures of gesture to which CDI scores can be compared. These do, however, associate closely with formally assessed aspects of language (i.e., comprehension; see Manual p. 109). CDI-WS *Complexity* has been compared to spontaneous speech transcriptions, with CDI M3L and other complexity scores associated strongly with MLU during unstructured play (Fenson et al.).

Predictive validity is considered in the 2nd edition Manual (Fenson et al. 2007), based on a subset of the normative sample which completed a second inventory form 6 months after initial assessment. For many, this entailed a repeat

assessment with the same form (i.e., 62 parents completed CDI-WG and 228 completed CDI-WS twice). For 217 cases, the interval necessitated initial use of the CDI-WG but follow-up using the CDI-WS. Predictive validity of expressive vocabulary counts was high for all infants and toddlers aged above 11–12 months at the first assessment, with best predictive power observed at an initial 20-month assessment. Only limited validity was shown for expressive skills in infants younger than 11–12 months and for receptive skills (only assessable at two time points for infants initially aged up to 12 months). This pattern of findings is argued to reflect a true lack of stability in the language skills of very young infants (a proposal supported by evidence from other areas of the developmental literature; see Fenson et al. 2007), rather than a flaw of the CDI-WG. CDI-WS grammatical complexity showed good predictive validity, particularly in children aged 20 months and older at initial assessment.

CDI-III

CDI-III normative data yield from 356 children aged 30–37 months. Given the relative recency of this form, only very limited psychometric data are available, summarized in the Manual (Fenson et al. 2007, pp. 154–160). Educational levels of respondents diverge significantly from US census data, limiting the confidence with which scores for children from low socioeconomic backgrounds can be validly interpreted.

CDI Short Forms

The 2nd edition Manual (Fenson et al. 2007) refers only briefly to the CDI-WG and CDI-WS Short Forms, available for purchase directly from the authors (for details, “See Also”). Preliminary normative data exist in a research publication (Fenson et al. 2000), with short-form and full-form vocabulary counts highly intercorrelated. The two (alternate version) level 2 Short Forms demonstrate important ceiling effects for toddlers older than 27–28 months, due to the abbreviated vocabulary list length containing only 100 words (vs. 680 words in the full CDI-WS).

Clinical Uses

Administration and Scoring

Administration of a full-version CDI form requires 20–40 min and should be self-explanatory to parents. While normative data collection was through postal return of forms, the Manual provides suggestions for clarifications to parents and procedures for checking report accuracy (Fenson et al. 2007, pp. 15–18). Both the CDI-WG and CDI-WS forms have norms for 16–18-month-olds, and form selection will therefore depend on the purpose of current and possible future assessments (see pp. 12–13). Options for scoring and obtaining normative CDI data (by hand or using automated methods) are discussed in detail (pp. 18–34). The authors address issues around data interpretation for three subgroups (pp. 34–38):

Children from low SES backgrounds (including where parental education is low)

Children who are learning more than one language

Children who are older than the normative group, but for whom language skills are within the assessable range of the CDIs

Parent-Report Pros and Cons

Parent reports are based on the everyday observation of child language and arguably produce more ecologically valid results than otherwise obtainable (e.g., through formal/direct assessment, naturalistic language sampling, etc.). CDIs benefit from the wealth of parent knowledge and are unlikely to be negatively influenced by aspects of the child's personality (e.g., shyness) or mood on a given day (e.g., fussiness). Clinically, parent report is also time efficient and cost effective; CDIs can be completed prior to attendance at more costly clinic appointments (i.e., permitting better use of the consultation time) and can be completed at multiple time points (i.e., to facilitate developmental monitoring; Fenson et al. 2007).

Other biases may be inherent, however. Parents may consistently over- or underreport their child's abilities, and the experience of

completing an inventory might influence later reports provided using the measure (i.e., through alteration of the parents' behavior with, or subsequent observation of, their child). However, such a possibility has been evaluated for the CDI, with minimal such influence observed (although such contention is more justified for parent reports on other aspects of child developmental skill; Fenson et al. 2007). Furthermore, the CDI format aims specifically to reduce potential respondent bias, addressing current and emerging skills (rather than past abilities) and using a recognition (rather than recall) format to minimize the effects of memory and item interpretation.

Clinical Uses for the Parent-Report CDIs

The Manual presents potential clinical and research uses of the CDIs (Fenson et al. 2007, pp. 40–46). While not uniformly accurate, and therefore inadvisably used in isolation of other information sources, CDIs should yield highly representative language characterization.

Screening for language delay. Firm diagnosis of specific language impairment (SLI) is possible only from around 3 years. However, CDIs permit assessment of conventional early markers for such language disorder (Fenson et al. 2007). Both “delay 3” (Rescorla 1989) and “delay 3+” (Klee et al. 2000) criteria for identifying late talkers can be gauged with the CDIs and associated Basic Information Form (Manual Appendix). Not all late talkers will develop enduring language problems. However, early identification of atypical developmental patterns may indicate further assessment and ongoing monitoring. Rates of communication *growth* (able to be evaluated through repeated CDI completion) better predict later language ability than do the results of any single assessment (Thal 2000). Delays in concurrent language comprehension and production accompanied by a failure to compensate with gestures signify particularly high risk (Thal and Katich 1996), with each component addressed within CDI-WG assessments.

Characterizing special groups. While the CDI normative sample extends only to 30 months

(37 months for CDI-III), they can be used to evaluate the skills of older children whose language falls within the range of assessed domains (i.e., developing vocabulary, emerging grammar, etc.). As such, they are increasingly used clinically/for research with individuals with autism spectrum disorders, Down syndrome, Williams syndrome, and cleft lip/palate, among other groups (e.g., Charman et al. 2003; Mervis and Robinson 2000; Snyder and Scherer 2004). Normative scores are only interpretable where older individuals' raw scores fall at or below the 30-month median level (Fenson et al. 2007). Raw scores are therefore typically of greatest interest (e.g., documenting how many raw words an individual understands/says).

Intervention design and evaluation. CDI results can identify specific intervention targets, such as the promotion of vocabulary growth, specific lack of comprehension skills, development of correct grammar, etc. Furthermore, the inventories can be used to evaluate/demonstrate post-intervention change. The Manual notes some such intervention studies including samples of toddlers with expressive language delays, with cleft lip/palate, and following cochlear implant (Fenson et al. 2007, p. 44).

References and Reading

CDI Advisory Board and Website

Additional materials and information on the CDIs, including contact details for purchasing the various publications and inventory forms, are available at: <http://www.sci.sdsu.edu/cdi>. This site is administered by the CDI Advisory Board, a not-for-profit organisation supporting further development of the inventories. Reference lists are included, concerning the various inventory forms and versions, and dating from the 1980s through early 2000s. Some relevant professional organisations, conference groups, and research groups are listed, and a dedications page honours Elizabeth Bates, a key CDI developer, who passed away in 2003.

Other-Language Adaptations

The website and Advisory Board play a key role in CDI other-language adaptations. Guidelines are provided for obtaining appropriate authorisation, and include requirements around the competence and resource-availability necessary to undertake adaptation. Suggestions regarding the adaptation procedure are outlined in an unpublished manuscript http://www.sci.sdsu.edu/cdi/suggestions_adaptations.htm (Dale et al. 1993). Other-language adaptations currently undertaken/underway are tabulated, and entries include investigator contact details, project website links, and publication reference lists (http://www.sci.sdsu.edu/cdi/adaptations_ol.htm).

Lex2005 Database

The Lex2005 Database (Dale and Fenson 1996), available on the CDI Website, (http://www.sci.sdsu.edu/cdi/lexical_e.htm) provides a month-by-month compilation of normative data for all CDI receptive and expressive *Vocabulary Checklist* items (in each of the English and Spanish [Mexican] versions). Users select the language, specific measure (i.e., receptive/expressive), types of word (i.e., all, specified semantic groups, specified words), and ages of interest, and the database returns the proportion of children at each age reported to understand/say each word of interest.

CDI Scoring Program (2004)

The website also allows users to download, free of charge, the *Scoring Program for the CDI (2004)*, with accompanying user's guide.: http://www.sci.sdsu.edu/cdi/scoringp_download.htm. The program aims to facilitate management of CDI data, including entry and scoring, and interfaces with PCs running Microsoft Office 97 or higher. The website mentions CDI Scoring Templates (http://www.sci.sdsu.edu/cdi/scoring_t.htm), and describes the types of scanner system required for automated scoring. Template configurations are indicated to be 'Coming Soon!' However,

like most of the website, this page notes its most recent update as February, 2006.

Communicative Functions

Sarita Austin

Unlocking Language, London, UK

Synonyms

Communication intentions; Communicative intent

Definition

Communicative functions refer to the purpose of gestural, vocal, and verbal acts intended to convey information to others. Some communicative functions include commenting, requesting, protesting, directing attention, showing, and rejecting. Gestures and vocalizations are often first observed as an indication of intentionality in infants 8–9 months of age. It is at this point many infants appear to begin pursuing their intentions through interactions with others. The development of communicative functions has been described by Bates as occurring in a sequence of three stages: *perlocutionary*, *illocutionary*, and *locutionary*.

The *perlocutionary* stage of intentionality begins at birth and is expected to continue until approximately 8 months of age. During this period, the infant focuses on objects and people and attends, discriminates, and responds to stimuli

through cries and coos. At this developmental level, the child does not possess the mental representational capacity to hold an intention in mind and convey it to another, but his behavior is interpreted and treated by caregivers as if it were intentional. As the predictability of interactions between the caregiver and child increases and cognitive development progresses, infants begin associating their actions with specific responses from their caregivers. Between 8 and 12 months, the *illocutionary* stage begins in which infants begin using gestures and vocalizations coupled with eye gaze and often repeating or modifying communicative acts in an intentional way to convey a message. In this stage, intentional, non-conventional gestures, such as tantrums, also begin to appear. Finally, the *locutionary* stage begins with a child's first meaningful word. This final stage of intentionality development typically occurs at approximately 12 months of age. During this stage, a child uses words in conjunction with gestures, sounds, and gaze to convey, at first, a limited range of communicative functions. As language and social-cognitive development proceed through the preschool and school years, a wider range of communicative intentions is acquired.

Community Services

Naomi Davis

Institute for Social Development, Cary, NC, USA

Synonyms

[Community-based services](#)

Definition

Community services include a range of programs that are designed to meet the support and intervention needs of individuals with ASD and their families. Services are delivered in community settings (e.g., community centers, recreational facilities, religious organizations) and include programs for individuals across the autism spectrum and throughout the life span.

The following list includes examples of community services:

- Case management
- Life skills training
- Structured social opportunities

- Employment training
- Community mentors
- Job counselors
- Respite caregiving services
- Recreational opportunities

Developmental Shifts in Service Use: Community service use often changes over time for individuals with ASD. Although children generally receive their primary services through their school, many families also make use of additional community services such as respite caregiving services (i.e., periodic, short-term in-home support to relieve primary caregivers) and specialized recreational activities to develop an area of interest (e.g., art, sports) or to foster a successful social experience (e.g., summer camps). Similarly, adolescents can take advantage of community services to increase their independence and preparation for the transition to adulthood (e.g., structured social activity groups, community mentors). For adults with ASD, specialized job training programs and employment counseling may be utilized.

Obtaining Service: Local and national ASD organizations often compile lists of available community services. These lists are intended to aid families in obtaining the most relevant services for their family member with ASD. Cost and payment requirements vary across services and by state, though many services may be available to individuals at low or no cost through existing Medicaid funding.

Research: In contrast to the accumulating evidence base for traditional interventions for ASD, less work has been done to evaluate the effectiveness of these varied community services. Families typically report involvement with multiple community services at a time to address different needs.

Definition

Community-integrated residential services are homes located in the community, rather than in disability institutions, and are designed to promote the social inclusion of people with disabilities. They developed as a challenge to the historical segregation and exclusion of people with disabilities from the community. People along the autistic spectrum historically were institutionalized in segregated state institutions, but the exposure of large-scale abuses in disability institutions and the growth of the disability rights movement prompted large-scale deinstitutionalization.

Historical Background

Eugenics and Segregation

In the late nineteenth and early twentieth centuries, eugenics and social Darwinism gained enormous popularity throughout the world. These ideas suggested that disabled people carried defective genes, labeling groups of developmentally disabled people (including people with autism) as “idiots,” “imbeciles” and “morons” – or lumped together through the term “feeble minded” (Noll and Trent 2004). People who were “feeble minded” were blamed for all sorts of social problems, including petty thievery, vagrancy, alcoholism, prostitution and illegitimate children – and they were regarded as a “burden” on society. These ideas, which are recognized as incredibly prejudicial today, were justified as “scientific” by medicine and

psychiatry at the time. Indeed, eugenics inspired a generation of scientists and was taught in 44 universities throughout the United States. The classification, pathologization, and devaluation of disability were integral to the scientific ideas of the time (Snyder and Mitchell 2006).

As a result of such negative attitudes toward disability, people with developmental disabilities were removed from the community and housed in institutions for the “feeble minded.” The following summary of attitudes toward disability highlights the extent of prejudice at that time. Common attitudes included regarding people with disabilities as subhuman, sick, menacing, pitiful, and a burden (Wolfensberger 1975).

Institutionalization and sterilization were linked in the eugenic agenda. By the 1960s, over 60,000 people had been sterilized in the USA (Kerr and Shakespeare 2002). Segregated residential institutions and educational institutions were more results of eugenic ideas. In total, the effect of eugenics was to create a widespread sense that people with disabilities were inferior, and perhaps dangerous, so they should be kept away from the community and locked in institutions.

Eugenic ideas were also central to the Nazi ideology. Their belief in “building a better race” stemmed in large part from the eugenic idea that it was possible to identify and eradicate those with “defective genes.” Under the Nazi eugenic program, “racial cleansing” and mass euthanasia resulted in mass genocide. People with disabilities were bussed into killing centers (rather than concentration camps), and they were diagnosed and killed on the day they arrived – a process which has been called “medicalized killing” (Lifton 2000, p. 14). Nazis sterilized 375,000 people with disabilities and killed approximately 275,000 children and adults with disabilities (Kerr and Shakespeare 2002, pp. 27–44).

Rationale or Underlying Theory

The rationale of community-integrated residential services for adults with autism stems from the

undercovering of the systemic and horrific abuses of congregate care in the late 1960s and early 1970s typified by the Willowbrook case. Willowbrook State Hospital on Staten Island, New York, became the symbol of the deinstitutionalization movement. The thought was that if patients lived and worked in the community, there will be less of a chance of abuse occurring because the eyes of the community were upon the caretakers in the small group homes. Furthermore, people with autism were warehoused in large state-operated psychiatric facilities along with individuals with serious mental illness. This was an inappropriate placement. They received little or no treatment, nor rehabilitation. Nor was the intervention or treatment specific to autism. By being integrated into the community, individuals with autism could learn adaptive behavior to become more independent than in a large institution.

Although the rationale for deinstitutionalization of individuals with autism and other disabilities outlined above is moral and sound, another rationale for community-integrated residential services for adults is economic. The cost of 24 h care in a large state-run psychiatric facility is staggering. Current estimates are between \$150,000 and \$200,000 per year per patient. Small community-integrated residential services, more commonly referred to as group homes, are a fraction of the cost of placement in a state psychiatric facility.

Goals and Objectives

The primary goal of any placement, whether it is a community-integrated residential setting or not, is safety. When evaluating a possible placement, an eye should be kept upon how the person with autism will be kept safe. Questions to ask include the following: (1) What are the staffing and supervision levels? (2) How is wandering prevented? (3) What is the staff training in the areas of (a) CPR, first aid, and the use of automatic external defibrillators; (b) medication management; (c) aggressive behavior management; and (d) psychiatric emergencies and crisis

intervention? (4) How are the residents transported to appointments and recreational activities? (5) Are there any geographic features in the community that might be hazardous to a person with autism (e.g., proximity to a highway, body of water, or railroad tracks)?

The second set of goals should involve maximizing the person's level of independence and integration into the community. The residential services should continuously be an opportunity for the person with autism to learn new independent living skills and adaptive behavior. These skills may be vocational in nature such as working or volunteering on a part-time basis. Or they may involve learning new skills like travel training skills. Instead of relying upon an agency van to drive the person with autism to and from work or recreational activities, the person can be taught how to use mass transit or call a taxicab. Depending upon the skill level of the individual, it may involve learning pedestrian skills. The person may learn to walk to and from the group home to a nearby store. This further increases his or her level of community integration and independence.

The final set of goals should revolve around improving the person with autism's quality of life. What can be done to increase the person's sense of connectedness? What can be done to foster their sense of self-advocacy? What kinds of activities or foods can be made available to the individual to bring joy to his or her life? What can be done to provide this individual with a high quality of life?

Treatment Participants

Community-integrated residential services are generally not considered a treatment in the traditional sense under a medical model. It is, however, a social intervention involving a number of individuals and agencies depending upon the age of the participant. As a part of the transition planning process under IDEA, the IEP team may identify living in a group home as a goal for the student with autism. The IEP team consists of the student with autism or another disability, his or her parents, special educators, and representatives of agencies other than the school district. The

representatives of other agencies can include either private not-for-profit social service agencies subcontracted by the state or state-run social service systems that are known by a variety of acronyms. These can be state offices of Developmental Disabilities Services, Offices of Mental Retardation and Developmental Disabilities (OMRDD), or Offices for Persons with Developmental Disabilities (OPWDD). (It should be noted that the term “mental retardation” is now considered a derogatory term and the preferred term is a “person with a developmental disability.”). These agencies will oversee the provision of residential services in the community. Other entities that may be involved include state offices of Vocational and Rehabilitative Services, Social Security Administration, Medicaid, and Medicare programs, as well as physical and mental health providers.

Group homes will have a variety of staff that are either permanently assigned to the home such as frontline workers or itinerant staff including psychologists, social workers, nurses, occupational therapists, recreational therapists, ABA specialists etc. The provision of services will vary from system to system. There are no universally set standards for the provision of community-integrated residential services for adults with autism. This will vary from state to state.

Treatment Procedures

Challenges to Institutionalization

One of the major reasons why institutionalization was abandoned as the major policy for housing people with disabilities was the public exposure of horrific abuses which were occurring in these institutions. Geraldo Rivera's exposé on the Willowbrook State School, a school in Staten Island for people with developmental disabilities, helped to raise public awareness about this issue. The school was filthy, overcrowded, unsanitary, and rife with physical and sexual abuse. In the words of one scholar, “Willowbrook (and by implication, other residential facilities of its kind) resembled concentration camps. Lacking

cleanliness, privacy, care, affection, and education, Willowbrook would soon become the nation's touchstone for publicly funded abuse and neglect” (Rothman and Rothman 2004, p. 445). A successful class action against New York State followed this public exposure of inhumane treatment.

Another important element of the Willowbrook case was the involvement of a group of scholars from Syracuse University. One leading scholar, Wolf Wolfensberger, developed a theory of “normalization” which suggested that people with disabilities should be afforded every right that other citizens have – they should attend regular schools, live in normal houses in regular communities, and be included in community activities such as leisure, recreation, and sporting events. This philosophy of normalization became a springboard for one section of the disability rights movement who strongly believed that institutions must be dismantled and their residents should be returned to the community. Institutions had become like incarceration, and they were totally inappropriate for people with disabilities, who deserved every opportunity to live a normal life in the community. In the context of the abuses occurring at Willowbrook, Wolfensberger and other scholars suggested that the residents of Willowbrook be immediately placed in group homes instead of the institution (Rothman and Rothman 2004).

The key principle of normalization has been summarized in the following way: “. . . the most explicit and highest goal of normalization must be the creation, support, and defense of *valued social roles* for people who are at risk of social devaluation” (Wolfensberger 2004, p. 43). The philosophy of normalization was later re-named “Social Role Valorization” and became an incredibly popular approach to disability, spurring on community-integrated residential living and giving a sense of what residential inclusion should look like.

Wolfensberger identified three consequences of the devalued social roles which had been attributed to people with disabilities. First, he said that mistreatment is an effect of social devaluation. This was his explanation for the abuse

experienced by disabled people: their devalued social roles encouraged people to treat them in ways that did not recognize their dignity. Second, he said that negative treatment is connected to the forms of devaluation: when people with disabilities are devalued as human beings and regarded as animals, they were put in cages in institutions. Similarly, people who are regarded as a menace will be surrounded by enclosures marked by locks, barred windows, fences, and so on. Third, he said that how people are treated greatly affects how they behave: when people are continuously treated as “deviant,” they will tend to adopt a deviant identity, but if they are treated with respect and dignity and are accorded valued social roles, they will adapt accordingly (Wolfensberger 2004). The implication of this argument was that people with disabilities needed to be located in the regular community – where people with valued social roles can be found – and that any institutions or patterns of behavior which diminished their humanity must be removed.

Wolfensberger believed that addressing the devalued social image of people with disabilities should occur alongside efforts to improve their “competencies.” He suggested that these two processes were interconnected:

A person who is competency-impaired is highly at risk of becoming seen and interpreted as of low value, thus suffering image-impairment; a person who is image-impaired is apt to be responded to by others in ways that impair/reduce his/her competency. . . a person whose social image is positively valued is apt to be provided with experiences, expectancies and other life conditions which generally will also increase his/her competencies, and a person who is highly competent is also more apt to be imaged positively. (Wolfensberger 2004, p. 45)

In conjunction with Social Role Valorization, an approach to evaluating community residences and services was developed entitled “PASSING,” which stood for “Program Analysis of Service Systems’ Implementation of Normalization Goals.” PASSING involved a questionnaire which could be used to evaluate the extent to which residences and services promoted valued social roles. They were evaluated according to whether the following features of the residence

or service enhanced the social role and competencies of people with disabilities: the physical setting of the buildings, the groupings and relationships built into the process, the ways in which time was used and activities were structured, and other miscellaneous areas (Syracuse University Training Institute for Human Service Planning Leadership and Change Agency 2007).

At the same time as the philosophy of normalization and Social Role Valorization was being developed, another key social change was occurring. The disability rights movement, modeled after the African American civil rights movement, was beginning to develop and assert the right to independent living. The first Center for Independent Living was formed in Houston in 1972, and Berkeley and Boston developed their Centers for Independent Living in 1974. Berkeley developed its national reputation from its unique perspective – emphasizing peer counseling, legal assistance, advocacy on access issues, and leadership by people with disability. For instance, disability advocates in Berkeley were able to get curb cuts installed around their city in the 1970s to make the whole community more inclusive and accessible (Fleischer and Zames 2001).

The development of the self-advocacy movement by people with disabilities represented a fundamental shift in the ways in which disability should be understood. No longer were doctors, social workers, welfare workers, bureaucrats, or allied health professionals considered the “experts” on disability; people with disabilities were claiming this role for themselves. Self-advocacy not only occurred among people with physical disabilities; people with developmental disabilities also formed organizations such as People First where they asserted their rights to make important decisions about their own lives (Shapiro 1994).

There were significant differences as well as similarities between the approaches of the emerging disability rights movement and those committed to the principles of Social Role Valorization. One primary goal of the disability rights movement was to remove barriers in the environment – whether those barriers are physical barriers such as steps or attitudinal barriers such as prejudice. But the assertion that people with disabilities must

be in charge of the entire process was not a part of the Social Role Valorization philosophy. It centered on human service and welfare professionals; the disability rights movement mobilized people with disabilities themselves (Linton 1998). Additionally, Social Role Valorization suggested that people with disabilities try to conform to socially valued roles; the disability rights movement asserted a completely different set of values from the rest of society and argued that society should conform to those values, not vice versa. Additionally, Social Role Valorization assumed that disability was generally a negative experience which should be minimized in order to allow the person to fit in to society; the disability rights movement began to promote disability pride, which emphasized and took pride in their differences rather than minimizing them (Sherry 2006).

The development of the disability rights movement had major implications for the ways in which community residential programs responded to the needs of people with disabilities. For instance, they had to begin with the assumption that people with disabilities are capable and did not need to be “fixed” or changed. Additionally, residential services need to provide support to enable people with disabilities, including people with cognitive and developmental disabilities, to control their own lives. Self-determination was now a key component of residential decision making (Mackelprang and Salsgiver 1999).

The deinstitutionalization process, and the growth of the disability rights movement, helped make independent living and supported living in the community a reality for many people with disabilities. Rather than being isolated from their friends and families in institutions, people with disabilities are now living in the community. Social inclusion, including community integration, allows people to make friendships and develop relationships with others and is a cornerstone of equal rights for people with disabilities.

Efficacy Information

The efficacy of community-integrated residential services is difficult to quantify because of the

multiple domains these services impact upon. It appears that these services were effective in moving people with autism out of a warehousing situation (as was the case in the large-scale congregate care) and into the greater community. It is a widely held belief that this move decreased the amount of abuse and neglect that was inflicted upon individuals with autism in large psychiatric hospitals. Likewise, it is believed that the deinstitutionalization movement allowed individuals with autism to receive more appropriate and autism-specific interventions that were empirically based. This led to better outcomes for individuals on the spectrum.

Community-integrated residential services have been effective in alleviating caregiver overload and burn-out. These services have also been effective when families have been overwhelmed with the behavior of the individual (e.g., assaultive or wandering behavior) or when the individual with autism’s parents have become too old and infirmed to care for their adult child. Further discussions regarding the efficacy of the services are dependent upon the particular outcome one is focusing upon.

Outcome Measurement

Outcome measurement is difficult to define in a traditional sense of a single intervention. Community-integrated residential services for adults with autism provide a variety of interventions across multiple domains of a person’s life. Some of the outcomes worth assessing are (1) the level of independence a person attains and the amount of support and supervision he or she might need; (2) the ability of the individual to navigate through the community and use mass transit; (3) the ability of the person to self-advocate when dealing with social service agencies, government entitlement programs, and health-care providers; (4) the skills necessary to manage money, pay bills, and purchase items at a local store; and (5) the frequency and quality of the person’s participation in community events, entertainment, and cultural festivities.

The literature is replete with references to a person being on a spectrum or a continuum when describing their abilities and deficits. Residential services likewise can be thought of as being on a continuum. On one end of the continuum is large-scale congregate care which is generally reserved for the individuals who are most severely impacted by symptoms of autism or have behaviors that prevent them from being in a less restrictive setting (e.g., aggressive/assaultive behavior or self-injurious behavior). On the other end of the continuum is an individual who lives in the community with no formal organization supporting his or her independence. This is done simply through informal support networks (e.g., friends, family, spouse, etc.). In between the two extremes of the continuum of care are group homes, supervised apartments where social service agency staff actually live in the apartment complex and are available 24 h a day/365 days a year for emergencies, and finally a situation where the individual with autism lives completely integrated within the community and social service agencies drop in periodically to help with bill paying, home maintenance issues, and possibly assisting in dealing with in-home emergencies (e.g., what to do if the circuit breaker is tripped; what do if a smoke detector is going off, how and when to use a fire extinguisher, etc.).

An adult with autism may move up and down the continuum of care depending upon where he or she is in the life cycle and how much intervention he or she receives to mitigate the symptoms of autism and any comorbid disorders. The ultimate outcome for any individual on the spectrum is to live in a residential setting that maximizes his or her independence and autonomy while simultaneously ensuring a reasonable level of safety.

Qualifications of Treatment Providers

The qualifications of treatment providers providing community-integrated residential services for adults with autism vary widely. This is a reflection of a variety of state laws governing the provision of residential services to persons with

developmental disabilities. The treatment providers may be state employees working for the Office for Persons with Developmental Disabilities, or they may be employees of a private not-for-profit social service agency. There are for-profit entities that provide care for persons with autism. When looking for a community-integrated residential placement for an adult with autism, consumers should ask where the agency receives its auspice. Who licenses the facility? Who inspects and regulates facility? How often are they inspected? These are all important questions to ask prior to placing an individual with autism into a group home or similar type of facility.

Comorbid ASD

► Risk of ASD in Individuals with Down Syndrome

Comorbidity

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

The presence of a second (comorbid) condition in association with a previous one.

Historical Background

The issue of comorbidity with autism has assumed increasing importance in recent years; it is intimately related to other issues including more general topics in diagnosis and classification as well as the attempt to identify meaningful approaches to subgrouping/subtyping autism. Clearly having any serious disability – such as autism or intellectual disability – only acts to increase vulnerability to other problems. In the past, as in the field of intellectual disability, the problem was complicated by the tendency of autism to “overshadow” other difficulties (Rutter 1994; Volkmar and Klin 2005).

Current Knowledge

Autism has been reported to co-occur with various other developmental, psychiatric, and medical conditions; however, often these associations are based on reports of single, or at best a handful of, cases and often fail to address the more central question of whether associations are observed at greater than chance levels. This has been strongly illustrated in the literature on associations of medical conditions with autism where early efforts, based largely on case reports, suggested hundreds, if not thousands, of such associations (Gillberg 1992), but more careful controlled studies suggested that this list is much smaller, with the strongest associations observed with seizure disorder and a handful of strongly genetic conditions (Rutter et al. 1994).

Evolving diagnostic concepts and research findings have sometimes clarified the significance or meaning of possible associations. For example, Kanner’s original impression (1943) that persons with autism had normal intellectual potential has been shown to be incorrect; although the pattern of cognitive and adaptive abilities in autism is unusual, for many of children with autism, overall scores on cognitive testing are stable within the mentally retarded range (Goldstein et al. 2008; Lord and Schopler 1989). On the other hand, a substantial group of persons with autism have cognitive abilities in the average or above average range and, with early diagnosis and intervention, the overall outcome (and levels of cognitive ability in adulthood) appears to be improving (Howlin 2007), suggesting that perhaps this association reflects an aftereffect of autism rather than one more essentially connected in an etiological sense to autism. On the other hand, seizure disorders of various types are frequently associated with autism if the latter is strictly defined occurring in perhaps 20–25% of cases.

Issues relating to comorbidity for other psychiatric conditions are complicated for several reasons. Firstly there is a major difference between approaches to diagnosis in DSM-IV and ICD-10. While both systems attempt to be comprehensive in coverage, ICD-10 comes from a nosological

tradition of searching for a single, parsimonious diagnostic label (i.e., a “top-down” approach more focused on syndromes rather than symptoms). Conversely DSM-IV and its predecessors have often seemed to encourage multiple diagnoses (a “bottom-up” orientation that starts with symptoms and then moves toward categories) (Ghaziuddin et al. 1992; Rutter 2006; Volkmar and Woolston 1997; Volkmar and Woodbury-Smith 2007). Clearly no single diagnostic label conveys the totality of the individual’s difficulties, and while the multiaxial approach employed in both DSM and ICD helps address this issue, tensions do remain regarding issues of additional diagnoses for persons with autism. Other issues arise given the changes that occur with developmental level and age. Issues of assessment are also a consideration, for example, what would it mean to assess thought disorder in a mute individual with autism?

Other issues arise given that diagnostic systems like DSM-IV and ICD-10 strive for logical consistency in their approach, that is, typically some form of hierarchical process is used so as not to reduce diagnosis entirely to the level of presence/absence of individual symptoms, for example, since stereotyped behaviors are a diagnostic feature of autism, it seems nonsensical to also give a diagnosis of stereotyped movement disorder to most people with autism.

Given these considerations, it is important to interpret reported associations with some caution, particularly if the association is based on case reports in large part. That being said, it is the case that a veritable host of conditions have been reported in individuals with autism. These include hyperactivity, obsessive-compulsive phenomena, self-injury, tics, and affective symptoms (Brasic et al. 1994; Ghaziuddin and Greden 1998; Ghaziuddin and Tsai 1991; Ghaziuddin et al. 1992, 1995; Jaselskis et al. 1992; Kerbeshian et al. 1990; McDougale et al. 1995; Realmuto and Main 1982; Rapoport et al. 2009; White and Schry 2011). Particularly in older and more able individuals, the presence of anxiety and mood

problems is quite frequent (White and Schry 2011). On the other hand, some disorders, notably schizophrenia, do not appear to be significantly increased in samples of individuals with autism (Volkmar and Cohen 1991).

In some cases, possible associations might have significance for treatment. For example, given the use of new pharmacological treatments such as the SSRIs, a possible overlap of autism with obsessive-compulsive disorder (OCD) would be of interest. Clearly phenomena suggestive of obsessions or compulsions are frequent (although highly variable depending on sample selected (Baron-Cohen 1989; Mack et al. 2010; Rumsey et al. 1985)) and may have implications for treatment (McDougale et al. 1995). However, as Baron-Cohen (1989) observed, it does appear that it is not possible to simply equate ritualistic phenomena of autism with the obsessions and compulsions more typical of OCD. Similarly reports of association with Tourette’s syndrome (chronic motor and vocal tics) are of interest, although data on whether or not such associations are more likely than would be expected based on chance alone have yet to be collected.

In recent years, considerable interest has centered on the association of autism with attention deficit disorder (ADD)/attention deficit hyperactivity disorder (ADHD) and the possible implications of such an association for treatment. Early views, as in DSM-III-R, questioned this association given the high frequency of attention problems in children with autism (particularly for social tasks) and what appeared to be, in general, a poor response to stimulant medications, although more recent research has questioned this view while also noting the potential for higher levels of adverse reactions in this population (Aman et al. 2008; Jahromi et al. 2009). The issue may have even greater importance among children with the broader autism spectrum (Barkley et al. 2002); attempts have been made to delineate specific subgroups of cases with problems in social interaction and attention (and other features, e.g., Hellgren et al. 1994).

Future Directions

Clearly the issue of comorbidity is an important one and one where our understanding is likely to significantly shift with advances in research. Complications arise from the dual, and sometimes competing, needs for research-based diagnostic approaches and one focused more on service delivery. In the United States in particular, issues of diagnosis may have very significant implications for eligibility for services. The ability in the coming years to more robustly identify end phenotypes may help resolve some of the issues.

Issues of comorbidity have become more relevant as overall outcome in autism has improved (in part because it becomes easier to document comorbid conditions using more traditional and conventional assessments). A growing awareness of this problem will likely produce a substantial increase in work in this area in the future.

Introduction

The present entry will present a brief introduction to diagnostic instruments commonly used in clinical assessments (and in research) of ASD and a comparison of these instruments. It is essential to distinguish between instruments designed to identify potential cases of autism spectrum disorder (ASD) for further clinical assessment (i.e., screening instruments for parents, teachers, pediatricians, and general practitioners) (Øien et al. 2019) and instruments designed to guide clinical judgment when an individual is referred for ASD specific assessment. Most commonly, a diagnostic includes a wide range of instruments to provide a developmental and behavioral context of understanding the symptom pattern presented at the assessment. Examples are the assessment of the individual's cognitive skills, adaptive skills. However, this entry is focused on instruments measuring autism-specific symptoms and guiding clinicians in the determination of ASD or not. It is of importance that trained professionals providing diagnostic assessments for individuals suspected of ASD, utilize appropriate measures, and are aware of the potentials and pitfalls of these instruments.

Current Knowledge

Since the introduction of the DSM-III and DSM-III-R in the 1980s (Volkmar et al. 1988), multiple

ASD specific diagnostic instruments were developed. Many of these instruments are validated in specific populations and cultures (Øien and Nordahl-Hansen 2018). As presented in the introduction, this entry will provide information about some of the most commonly used ASD-specific diagnostic instruments and the performance of these instruments. Since the introduction of the DSM-III, multiple instruments for diagnosing ASD have been developed.

However, these instruments must not alone serve as a conclusion for clinical decision-making but rather as tools used for guiding clinical judgment.

One of the difficulties with the development of diagnostic instruments for ASD is the heterogeneity of onset and patterns of symptoms and the variability in the severity of both symptoms, IQ and adaptive skills (Klin et al. 2005). This causes significant challenges in the development of one instrument expected to perform well in identifying ASD across the continuum. For more in-depth information and psychometric properties about the various diagnostic instruments Corsello (2013) (Encyclopedia entry on diagnostic instruments). Examples of the most used ASD-specific instruments are:

Interview-Based Instruments

In terms of interview-based instruments, the present entry highlights two, whereas one (ADI-R; Lord 1994) is the most commonly used diagnostic interview.

Diagnostic Interview for Social and Communication Disorders (DISCO; Wing et al. 2002)
It is constructed as a semi-structured interview of parents (primary provider) to diagnose autistic disorder, Asperger’s syndrome, psychiatric disorders, and other developmental disabilities. It is extensive, with over 300 items, whereas 93 items are used for diagnostic guidance. The DISCO is scored from 0 to 2, whereas a lower score indicates more abnormal development.

Instrument item rating	Value
0	Severe problem
1	Minor problem
2	No problem

The scale is furthermore divided into different domains:

Domain	Number of items
Social interaction	38
Communication	15
Stereotyped behaviors	29

The Autism Diagnostic Interview-Revised (ADI-R; Lord 1994)

The ADI-R is a semi-structured interview that contains 93 items concerning behavior at different ages.

The ADI-R has an opposite scoring than the DISCO and is scored as follows: which are scored between 0 and 3, plus additional scoring possibilities. The rating scale includes the following scoring options:

Instrument item rating	Value
0	The behavior of the type specified in the coding is not present
1	The behavior of the type specified is present in an abnormal form, but not sufficiently severe or frequent to meet the criteria for two
2	Definite abnormal behavior
3	The extreme severity of the specified behavior
7	Definite abnormality in the general area of the coding, but not of the type specified
8	Not applicable
9	Not known or asked

The ADI-R is validated and includes four different domains: reciprocal social interaction,

language and communication, stereotyped repetitive behaviors or interests, and age-of-onset criteria.

Cutoff scores are for each domain as following:

Domain	Cutoff score
Social interaction	10
Language and communication	8 (verbal) 7 (non-verbal)
Stereotyped repetitive behaviors or interests	3
Age of onset	1

It is essential to keep in mind that these criteria are tailored to the criteria in ICD-10 or DSM-IV-TR diagnosis of “F84.0 Childhood autism” (WHO 1992) or “299.00 Autistic Disorder” (APA 2002).

Også laget en småbarnsalgoritme for bruk ved ADI-R.

Observation-Based Instruments

The Autism Diagnostic Observation Schedule
The ADOS-G was introduced in 1989 (Lord et al. 1989), later updated to the ADOS-2 (Lord et al. 2012) and is a semi-structured, observer-based instrument that can only be performed by a trained clinician. The procedure is constructed as a standardized play and communication sessions, and the observed behavior is rated 0–3. ADOS2 consists of four different modules, and which one to use is guided by the individual’s level of expressive language and chronological age.

Module	Usage	Number of items
1	Little or no phrase speech	29
2	Phrase speech, but not fluently	28
3	Fluent children and young adolescents	28
4	Fluent adolescents and adults	31

Comprising five different domains:

- Domain
- Language and communication
- Reciprocal social interaction
- Imagination
- Stereotyped behaviors and restricted interests
- Other abnormal behaviors

Gotham et al. (2007) proposed revised algorithms for module 1–3, to increase specificity in determining an ASD diagnosis in lower functioning populations, that was taken into consideration in the ADOS-2 (Lord et al. 2012).

Comparison of Diagnostic Instruments

The diagnostic process can be time-consuming depending on the age of the child/adolescence, complexity of development/difficulties, and presence of comorbidity. Comorbid conditions might cause the symptom expression to be higher as many of the difficulties associated with ASD is not ASD specific. As mentioned, clinicians rely on different tools such as the ADOS and the ADI-R to assist the clinicians in the diagnostic process. While there is a range of instruments designed for autism-specific diagnostic assessments, few of the instruments perform excellently in psychometric properties alone. Current knowledge indicates that the use of autism-specific interviews with parents and caregivers lack the psychometric properties alone to be regarded as “good enough” on their own. However, the combined use of the ADOS and ADI-R are regarded as the gold standard of diagnostic instruments but do require extensive clinical expertise and reliability (Falkmer et al. 2013). According to Falkmer et al. (2013), the ADOS and ADI-R showed that these instruments performed better than any of the other instruments in terms of sensitivity and specificity, i.e., the accurately identifying children with ASD and distinguishing them from children with other developmental issues, combined showing a classification rate of 88%. However, it is crucial to address the fact that diagnostic instruments areas the term indicate: instruments used in a more extensive assessment. Interpreting the results from any

instrument should be conducted with caution, and sound clinical judgment should be penalized in the diagnostic process. Determining ASD by an instrument should be disregarded, and the clinician should always use the instrument as an aid in securing the optimal diagnostic result possible.

In terms of diagnostic performance, a study utilizing the Norwegian Mother and Child cohort, and its nested sub-study the Autism Birth Cohort revealed that the ADI-R cutoffs demonstrated good specificity (SP), while showing lower sensitivity (SE), i.e., missing approximately 43% of toddlers where parents did not have any specific concern about autism spectrum disorder. Furthermore, the same study by Havdahl et al. (2017) revealed that the ADI-R and the ADOS scores agreed well with clinical diagnoses (AOC > 0.85). However, as Havdahl et al. (2017) highlight, the different cutoffs for the ADI-R were needed in the presence or absence of parental concern to achieve comparable SE and SP.

Current results from the ADI-R and ADOS highlight the importance of good clinical judgment and the importance of taking parental concern seriously in the diagnostic process and when interpreting scores from parent endorsed instruments such as the ADI-R and consequently the DISCO. As presented in Havdahl et al. (2017), combining instruments such as the ADI-R and the ADOS provides the optimal prediction and clinical guidance in diagnostic processes (Havdahl et al. 2017).

Future Directions

There is a pressing need to understand how the various instruments, not only the ADOS and the ADI-R, perform across various populations, ethnicities, and cultures. However, it also how the instruments perform in terms of each other. The ADOS and the ADI-R are currently regarded as gold standard instruments, but the gold standard should be considered as relative rather than absolute (Øien et al. 2018). Further research is needed to ascertain how well the parent endorsed instruments are performing in cases without parental concern and for children within the average

range IQ. It is crucial to think about diagnostic instruments such as 3di, DISCO, ADOS, and ADI-R as a supplement and helpful tool in the diagnostic process rather than a tool providing a conclusive decision regarding diagnosis.

Comparison of High-Functioning Autism and Asperger Syndrome

Lucia Margari, Concetta de Giambattista and Patrizia Ventura
Child Neuropsychiatry Unit, University of Bari
“Aldo Moro”, Bari, Italy

Definition

Since Hans Asperger’s first description, through Lorna Wing’s translation and definition, to its introduction in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), Asperger syndrome has always aroused huge interest and debate, until vanishing in the DSM fifth edition (DSM-5).

The following entry will describe the history of Asperger syndrome, from the original description to the current diagnostic classifications, focusing on clinical profile, boundaries with high-functioning autism and nosographic implications.

Historical Background

In the same years of Leo Kanner’s description of infantile autism (Kanner 1943), Hans Asperger wrote a case report on autistic psychopathy (Asperger 1944), describing children with social-communication impairment, eccentric manners, unusual interests, and cognitive domains of hyperfunctioning. The American Psychiatric Association (APA) did not immediately recognize Autism as a distinct category: it was introduced as infantile autism in the third edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-III) and included within pervasive developmental disorders (PDD) in the DSM-III-R. In 1981, Wing resumed Asperger’s researches, renaming the autistic psychopathy as Asperger syndrome (AS) (Wing 1981). In 1989, the first diagnostic criteria for AS were proposed (Gillberg and Gillberg 1989; Szatmari et al. 1989), and in the 1990s, AS appeared in the fourth edition of DSM (DSM-IV) within PDD. The diagnosis of AS required at least two symptoms of social interaction impairment and one symptom of behavioral and interest restriction, a normal cognitive functioning, and the absence of significant general delay in language. Moreover, diagnostic criteria for autistic disorder should not be met (otherwise, autistic diagnosis should have precedence). This implied a differential diagnosis between AS and autism, especially the type without cognitive delay, also known as high-functioning autism (HFA). HFA is not a term used in the DSM, but it is commonly used to identify subjects diagnosed with autistic disorder (AD) or PDD-not other specified (PDD-NOS), with average or above average intellectual abilities (intelligent quotient, IQ, higher than 70). HFA differs from low-functioning autism (IQ lower than 70) in terms of clinical presentation, prognosis and need for support and assistance in daily

life. Since AS and HFA are both characterized by a normal cognitive functioning, there has been considerable debate over whether AS and HFA are distinct conditions, suggesting different etiological and neurobiological mechanism, or share a similar underlying neuropsychological functioning and should therefore be regarded as variants of a single disorder. According to Hans Asperger original description, his patients differ from those described by Kanner (Asperger 1944). Instead, Lorna Wing, translating Asperger's work, named the syndrome and Kanner's autism both part of an autistic continuum (Wing 1981). AS definition and its boundaries with HFA have been the topic of a growing body of literature, providing contradictory results: some authors considered the available evidences insufficient to establish the validity of AS as a syndrome distinct from HFA; others found quantitative rather qualitative differences between them. Sharma et al., in a review of 69 research studies, published from 1981 to 2010, defined "confuse and inconsistent" AS diagnosis, since it is based on criteria mostly overlapping with autism, from which though it could stand out for some fine differences in the nature of social interaction and communication (Sharma et al. 2012).

The unsolved confusion in defining AS criteria and the clinical overlap between HFA and AS led to its merging into one unifying category, on the assumption that they cannot be reliably differentiated from one another; the DSM-5 incorporated AS into autistic spectrum disorder (ASD), removing the previously discrete diagnostic presentation of PDD. According with members of the DSM-5 Neurodevelopmental Disorders Committee, the application of DSM-5 criteria demonstrated adequate sensitivity across all PDD subcategories, also including subjects denoted as cognitively higher functioning and AS (Huerta et al. 2012).

Current Knowledge

Irrespective of the DSM-5 changes, several studies (also published later than 2013) continue to debate about AS and its conceptualization within ASD (Volkmar and McPartland 2014).

Tsai and Ghaziuddin (2014), finding in 95 of 125 comparative studies quantitative and qualitative differences between AS and HFA, expressed their concern about the risk that with the single category of ASD, DSM-5 "moved forward into the past."

A recent study conducted a comparison between 150 children and adolescents with diagnosis of PDD, according to DSM-IV Text Revision (DSM-IV-TR) criteria, with an intelligent quotient average or above, among which 80 AS and 70 HFA (including patients with a diagnosis of autistic disorder or pervasive developmental disorder-not otherwise specified), in term of core clinical features, cognitive functioning, school learning abilities, and comorbidities (de Giambattista et al. 2019). Core clinical features were investigated using the Australian Scale for Asperger's Syndrome (ASAS) (Attwood 2006) and the Michigan Autism Spectrum Questionnaire (MASQ) (Ghaziuddin and Welch 2013). Administering ASAS, social abilities resulted impaired in both groups, even if HFA appeared more compromised above all in avoiding social contact. AS can show more motivation to socialize and desire for friendship, even if this does not translate into superior ability to make friends, because they appeared awkward, eccentric, one-sided, and insensitive. Emotional dysregulation was another common feature in AS and HFA, resulting in need for excessive amount of reassurance and problems especially regard to anger and anxiety management. Among communication abilities, both the conditions presented some deficits in reciprocity of conversation, eye-contact, and modulation of voice tone; nevertheless, over-precise and pedantic speech (characterized by overly formal speech, similar to an in-depth monologue about a topic of special interest, verbose and tangential, lack of the normal prosody, enriched by a sophisticated vocabulary) was significantly more frequent in AS and literal interpretation of comments more common in HFA. The first finding ("over-precise or pedantic speech") is unsurprising and represents one of the most typical clinical feature of AS, firstly described by Hans Asperger's original work (1944, in which

AS were called “little professors” for their way of talking), then included in the following proposed diagnostic criteria sets (Gillberg and Gillberg 1989; Szatmari et al. 1989) and confirmed by subsequent studies (Woodbury-Smith and Volkmar 2009). The second finding (“literal interpretation of comments”) may be related to the HFA worse cognitive and comprehension abilities, which made them less able in recognizing the speaker’s communicative intention and in social understanding, unlike patients with AS, who adopted intellectual strategies of compensation.

Delay in language development resulted significantly more common in HFA, even if also in AS, a mild language delay was reported. In the DSM-IV-TR, the “absence of clinically significant general delay in language (e.g., single words used by age 2 years, communicative phrases used by age 3 years)” was a relevant criterion for AS diagnosis. In contrast with this theoretical construct, extensive literature data showed that language delay could not be considered as a diagnostic exclusion criterion for AS because subtle language problems are expected in AS and also because the recognition of a language delay is not always enough reliable, since it is often dependent on parents recall. Clumsiness, that has been originally considered a distinctive feature of AS appeared indifferently present in AS like in HFA, as well as sensory abnormalities (such as unusual fear/distress due to light touch on skin or scalp, and to unexpected noises), restrictive pattern of interests and behaviors, and difficulties in adaptation to changes. The clinical profile of AS is less likely to include motor mannerism and preoccupation with parts of objects (defined “low order repetitive restricted behaviors”) while more often presented circumscribed interests that consumes a great deal of their time amassing information and facts (defined “high order repetitive restricted behaviors”).

About cognitive functioning, evaluated with Wechsler scales, AS showed Full Scale Intelligence Quotient mean values and sub-values significantly higher than HFA, without differences between verbal and performance sub-values. This overall better performance in AS represented a well-established mark of

differentiation between AS and HFA. Indeed, some authors identified a qualitatively distinct cognitive profile (characterized by a higher verbal IQ and a lower performance IQ and a reversed pattern in HFA), while others reported mixed cognitive patterns. The two conditions could likely be distinguished at a quantitative cognitive level, represented by FSIQ, rather than at a qualitative level, represented by specific cognitive profile. Nevertheless, as for intellectual disability, the presence of very different IQs could denote distinct levels of severity and clinical profile, in the same way a large discrepancy between AS and HFA intellectual scores could have a qualitative effect on general function.

Learning disorders resulted significantly more frequent in HFA, with the exception of dysgraphia, that emerged frequently in both groups, according to the original description of Hans Asperger (Asperger 1944), who described in his patients low performances in handwriting, in terms of forming letters and using the paper space. AS may not show any conspicuous learning disturbances, but an inhomogeneous school profile, characterized by talents in some school subjects, such as precocious learning to read, numerical abilities, or memory, while poor application and performances in other school subjects, perceived as less interesting.

The most prevalent comorbidity both in AS and HFA was attention deficit hyperactivity disorder (ADHD). An association between ASD and ADHD and other externalizing disorders have been reported and supported by clinical population research and twin studies, suggesting substantial genetic overlap (Taylor et al. 2015). Considering that comorbidity between these disorders was a relevant and frequent occurrence, differently from the previous edition, DSM-5 allowed the diagnosis of ADHD in the context of an ASD. Subjects with AS displayed more anxiety and depressive symptoms compared to HFA. This could be explained with AS higher cognitive and communicative levels, that made them more able in introspection, more “active but odd” (Ghaziuddin 2008) in relations attempts, more conscious of social difficulties and so more vulnerable to affective disorders.

Overall, among AS and HFA, differences in neurodevelopmental trajectories and subsequent need for health service could be recognized. Clinical signs in AS might be subtle and camouflaged in preschoolers and could become clear at the age of 7 or 8 years, leading to a later diagnosis.

Another focus of debate is the effect of DSM-5 criteria application on high-functioning ASD. Recent studies indicated a percentage between 50% and 75% of individuals maintaining diagnosis under DSM-5 criteria (Smith et al. 2015). A so wide concordance range could reflect diagnostic methodologies adopted in different studies: the gold standard diagnostic instruments for the assessment of autistic disorder could have low sensitivity when applied to high-functioning subjects. Clinical judgment of qualified professional experts and the use of specific rating scales, designed on the clinical characteristics of HFA and AS, may contribute to reduce the risk of underdiagnosing. According with this perspective, the study of de Giambattista et al. (2019) provided evidences that using brief and simple screening instruments such as ASAS and MASQ, it is more likely to recognize specific features of HFA functioning: indeed, 97.3% of the subjects, previously diagnosed according to DSM-IV-TR, met DSM-5 criteria for ASD and administrating MASQ different scores in HFA and AS were found. Moreover, when DSM-5 specifiers of severity levels were applied to the sample, HFA were more frequently classified in Level 2 (“requiring substantial support”) than AS, while AS were more frequently classified in Level 1 (“requiring support”).

Future Directions

Considering available evidences, it is likely to assume that a complex aged-related different developmental profile between HFA and AS exists, characterized by quantitative and subtle qualitative differences such as language development and communication style, cognitive functioning, academic achievement, and comorbidities profile.

Consistently with clinical findings, biological patterns of differentiation were found: a recent genome-wide association meta-analysis revealed evidences for a qualitatively different genetic architecture between subtypes of ASD (Grove et al. 2019), differences in neuroimaging field, in particular in gray matter distribution (Bi et al. 2018), and in EEG connectivity patterns (Luckhardt et al. 2014).

While acknowledging the merit of the DSM-5 to have solved lots of previous classification discordances and “splitting” approaches (Volkmar and McPartland 2014), it is necessary to consider the risk that defining autism using the umbrella term ASD, could hide its evident heterogeneity (Lai et al. 2013) and particularly that in the severity specifier “Level 1” of the DSM-5, many phenotypic variances could be squeezed making this level very heterogeneous.

It is likely that recognition of different “nuances” of the spectrum may contribute to tailor research, clinical, and assistential approaches. For example, since language development and academic abilities play a central role in global functioning during the first years of life, HFA require more support in terms of rehabilitative treatments and school educational needs than AS, while in middle childhood and adolescence, AS require more support in terms of psychotherapy, presenting more emotional and mood problems than HFA.

Several expert researchers and specialists in the field have invited to reflect about the consequences of removing AS from the available classification, just when it was better understood by the society: the lack of a “label” in which subjects recognized themselves might cause confusion and damage the identity sense of the yet established “Aspie community” (“Aspie” is an affectionate term often used to describe a person with an AS diagnosis or profile).

Future direction in the field of ASD categorization could move forward in the identification of subtypes within the autism spectrum: “subtype specifier” and “partial remission specifier” could promote progress in autism research and improve clinical practice.

DSM-5 allows to use specifiers of language and intellectual impairment that resulted enough restricted to distinguish clinical profile of HFA from classical, low functioning, autism. Nevertheless, a “subtype specifier” for AS could be useful to hypothesize putative developmental trajectories and direct specific paths of treatment.

Moreover, recent theories of neurodiversity, accompanied by the preference of the more neutral term of autism spectrum condition (ASC) rather than ASD, consider AS as a natural variation rather than a syndrome. In fact, AS subjects could, in particular conditions (“Aspie-friendly” or in preschool age), temporarily lacked significant global impairment. Their phenotypes may be considered subclinical-AS-forms. Nevertheless, in most cases, these subjects need a sort of support (cognitive-behavioral treatment, parent/teacher psychoeducation, personalization of school program), also for preventive purpose only. As in ADHD coding of DSM-5, regarding level 1 ASD patients, it could be suggested the use of “subclinical” specifier, for those patients who express only subthreshold autistic-traits and “partial remission” specifier, for those patients who do not meet currently the full diagnostic criteria.

In conclusion, even continuing to use the broad category of ASD, it could be meaningful to introduce, in future revisions of the manual, subtype specifiers that could capture the “nuances” of the spectrum.

Future research about the efficacy of these prospective specifiers could be beneficial.

COMPASS for Hope Training Program

Grace Kuravackel¹ and Lisa Ruble²

¹Pediatrics, University of Louisville,
Louisville, KY, USA

²Educational School and Counseling Psychology,
University of Kentucky, Lexington, KY, USA

Definition

COMPASS for Hope (C-HOPE) is a manualized parent-mediated intervention for children with challenging behavior and autism spectrum disorder (ASD). C-HOPE is based on an existing clinical decision-making framework known as the Collaborative Model for Promoting Competence and Success (COMPASS; Ruble et al. 2012). C-HOPE has effectiveness for telehealth or in-person delivery for decreasing behavior problems in children with autism spectrum disorder (ASD), increasing parent competency, and decreasing parent stress.

Historical Background

C-HOPE comes from COMPASS, a validated intervention that has been tested in randomized controlled trials (RCTs) and 20 years of work (Ruble and Dalrymple 1996) in public schools. COMPASS stands for Collaborative Model for Promoting Competence and Success and is an alternative framework for conceptualizing, assessing, and intervening to improve outcomes in autism based on a transactional approach (Fiese

and Sameroff 1989; Ruble and Dalrymple 1996) that considers the complex interplay between the individual, family, school, social, community, and economic resources – the critical proximal (i.e., closely connected to the individual) and distal influences and interactions between individuals with ASD and their environments. We first tested COMPASS for preschool and elementary age students as a consulting intervention to improve IEP outcomes with a large effect size (1.1) compared to IEP outcomes of students receiving services as usual (Ruble et al. 2010). In a second RCT, we replicated our findings and also demonstrated the efficacy of web-based coaching in COMPASS (Ruble et al. 2013). The third RCT, COMPASS for Transition (COMPASS-T), was tested with high school students in their final year of school with a focus on improving IEP and postsecondary outcomes (Ruble et al. 2018). A very large effect size (2.1) was observed for IEP goal attainment outcomes based on an independent observer.

Rationale or Underlying Theory

ASD is a neurodevelopmental disorder that presents many challenges for parents as well as teachers, therapists, and other professionals, often in part because of challenging problem behavior (Crone and Mehta 2016). These problem behaviors are secondary to, or exacerbated by, the core symptoms of ASD [Centers for Disease Control and Prevention (CDC) 2012]. The presence of problem behaviors impacts both children and their families. For children, they experience fewer community outings, less positive interaction with peers, and less access to intervention and education (Anderson et al. 1992; Matson and Nebel-Schwalm 2007). For parents, they report a greater sense of helplessness compared to parents of neurotypical children (Pisula and Kossakowska 2010). A meta-analysis conducted by Hayes and Watson (2013) suggests that the overall level of problem behaviors accounts for the most variance in explaining parent stress when compared to other child factors, such as IQ, autism severity, and adaptive skills, a finding confirmed by others (Krakovich et al. 2016).

Thus, we developed C-HOPE from the existing COMPASS framework to target three outcomes: decreased parent stress, decreased child problem behavior, and increased parent competency. COMPASS is unique in that it focuses on ASD-specific goal areas of social communication skills meaningful for quality of life (QOL). COMPASS is based on the developmental theory that competency is the result of reciprocal and dynamic interactions between individuals and their environments (i.e., transactional) (Ruble and Dalrymple 1996). Thus, if we can carefully examine and identify the contribution that the environment makes toward reducing individual risk factors and enhancing protective factors, we can influence the development of important QOL skills. Competence looks different across the lifespan and is person-specific. Thus C-HOPE behavior plans are sensitive to the specialized learning needs of individuals with ASD and the required instruction across social, communication, and learning skills competencies to continue to be refined and utilized throughout development into adulthood. Further, the extreme heterogeneity in ASD requires a framework, like COMPASS, that can be helpful independent of the language, cognitive, or social abilities of individuals with ASD.

Another unique dimension of C-HOPE, that separates it from other parenting programs, is the emphasis placed on a collaborative, strengths-based approach in working with families. C-HOPE is delivered in an individual and a group format. The group format is intended to be therapeutic as well as educational and draws upon the concept of universality (“I am not the only one struggling”; Yalom 1995) and offers the opportunity for families to also provide emotional support to others and to feel less isolation. C-HOPE requires that the facilitator(s) draw upon basic counselling skills that promote active listening and empathy. Facilitator(s) also have to be aware of group process for the purpose of promoting cohesion among members and to ensure that the goals and needs of the group are met. The importance of a strong therapeutic alliance is foundational to a good helping relationship (Crits-Christoph et al. 2009; Zuroff et al. 2010).

Goals and Objectives

C-HOPE is designed to promote positive parent *and* child outcomes, including decreased child problem behavior, decreased parent stress, and increased parent competency using an evidence-based practices in psychology (EBPP) framework such as COMPASS (McGrew et al. 2016). Parents are the primary intervention targets in C-HOPE. COMPASS emphasizes clinical decision-making based on the three elements of an EBPP-informed approach of child preferences and strengths, parent and family resources, and evidence-based practices. Through positive parent-therapist collaboration, utilizing the COMPASS framework, direct training and support are provided in order to facilitate parent-implemented behavior intervention plans.

Treatment Participants

C-HOPE was developed for parents of young children with ASD and/or intellectual disability or other comorbid diagnoses. C-HOPE is most suited for parents of children between the ages of 3 and 12 years who also experienced challenging behavior. C-HOPE was developed for in-person or telehealth delivery. Thus, parents who are unable to attend in-person sessions may benefit, and this can be a tremendous benefit for families in areas where local resources are scarce.

Treatment Procedures

The C-HOPE curriculum includes activities that support parent-to-parent interaction as well as parent knowledge and skill and include four individual sessions (1 h) and four group sessions (2 h). Prior to the start of the treatment sessions, parents complete a COMPASS profile (see Ruble et al. 2012). The profile guides the discussion for the first individual session and assists with clarifying the problem behavior and possible underlying communicative intents behind the behavior. Once the purposes of behavior are understood, goals are developed that target replacement skills

to increase positive behaviors and decrease problem behaviors.

Individual sessions primarily focus on developing, implementing, and fine-tuning the individualized behavior plan that describes the identified problem behavior(s) and replacement skills. After developing a common understanding and language (e.g., joint attention, antecedents, consequences) to describe child skills, parenting practices such as encouraging positive child behaviors and how to use supports proactively to decrease challenging behaviors are written into the behavior plan. Emphasis is placed on using positive behavior supports (i.e., environmental manipulations) that are designed to promote pro-social skills effective in reducing disruptive behaviors for children with ASD (Buschbacher and Fox 2003; Iovannone et al. 2003; National Research Council 2001; Turnbull et al. 2002). Behavior plans included understanding the antecedents or causes of behavior, making the behavior ineffective, teaching replacement skills that result in desired outcomes for the child, and rewarding positive skills.

The group sessions provide basic information on ASD, including discussion of the learning differences specific to ASD, as well as how these learning differences impact behavior, socialization, and communication of their child. Typically individual sessions follow group sessions so that information learned in group session is discussed and considered during the individual session so that behavior plans are fine-tuned as new information is learned. Psychoeducation also includes information on evidence-based approaches for problem behaviors such as functional behavior assessment including antecedent manipulation, changes in instructional context, differential reinforcement, and self-management strategies (Braithwaite and Richdale 2000; Buggley 2005; Frea et al. 2001; Keeling et al. 2003; Schilling and Schwartz 2004).

In addition, group sessions target parent stress and coping skills. A variety of coping strategies for parental stress are presented, and parents are asked to identify what strategies they find helpful and what new strategies they would consider using in the future. Coping strategies include

general stress reduction techniques, mindfulness-based interventions, and relaxation strategies that have been shown to have long-term positive effects on stress levels and psychological well-being of parents of children with ASD (Cachia et al. 2016).

Order of sessions and content of each individual and group session can be retrieved from Kuravackel et al. (2018). The C-HOPE manual outlining all session details can be requested from the authors.

Efficacy Information

C-HOPE has been tested in two studies. The first was a randomized wait list design that tested telehealth vs face-to-face delivery of C-HOPE. The second was a pre-posttest design that tested an online-only condition where parents met virtually rather than in person (Kuravackel et al. 2018; Rodgers 2018). Both studies examined outcomes of C-HOPE on variables of child problem behavior, parent competency, parent stress, group alliance, and parent satisfaction. Results from the first study indicated significant between-group differences between the treatment and control. Further, pre-posttreatment gains in child problem behavior scores, parent competency, and parent stress were observed for the C-HOPE group. Telehealth modality was equally effective as face-to-face intervention, and no differences were detected with regard to group alliance or parent satisfaction in either modality. Overall parent satisfaction was high across both telehealth and face-to-face modalities (Kuravackel et al. 2018). For the second study when C-HOPE was tested with the group session meeting virtually and the individual sessions conducted using telephone, significant improvements were noted in parent stress and child behaviors and no changes for parent competency (Rodgers 2018).

Outcome Measurement

For primary outcomes of reduced parent stress, increased parent competency, and reduced child

problem behavior, the following were used, respectively: the Parental Stress Index-Fourth Edition Short Form (PSI-4-SF; Abidin 1995) to measure parent stress, the Eyberg Child Behavior Inventory (ECBI; Eyberg and Pincus 1999) to measure child problem behavior, and the Being a Parent Scale (BPS; Johnston and Mash 1989) to measure parent competency. For the secondary outcomes of parent satisfaction and group alliance, the following measures were used, respectively: Consultation Satisfaction Questionnaire (CSQ; Ruble et al. 2010) and the Group Session Rating Scale (GSRS; Duncan and Miller 2007).

Qualifications of Treatment Providers

C-HOPE therapists should have a background in a field that provides mental health intervention services (e.g., clinical/counseling/school psychology, rehabilitation psychology, social work). Therapists who participated in the initial trial of C-HOPE included those with the following backgrounds: doctoral students in school psychology and licensed psychologists. C-HOPE therapists should have prior experience working with parents and clients with ASD, implementing behavioral interventions, and familiarity with evidence-based interventions recommended for ASD. It is recommended that therapists new to C-HOPE receive supervision of their first C-HOPE intervention. A manual has been developed for further reading and intervention fidelity and is available from the authors.

Competitive Employment

David J. Krainski

Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA

Definition

Competitive employment is work that is performed on either a full- or part-time basis in which individuals are compensated for their work.

The compensation paid must be at or above the set minimum wage, but not less than the wages paid to individuals who are not disabled and performing work that is the same or similar. The individual must be employed in an integrated setting in which the individual has the ability to interact with individuals who are not disabled ([NYSED.gov](http://www.nysed.gov), 2011).

Historical Background

Historically, competitive employment was not considered a likely outcome for individuals with autism spectrum disorders (Wehman et al. 2003). Typically, individuals with disabilities were placed in segregated or sheltered vocational settings in which they worked among other individuals with disabilities only to be supervised by non-disabled individuals (Lutfiyya et al. 1988). These sheltered settings were considered to be transitional with the hopes that most individuals placed in these environments would transition into competitive employment. However, Taylor in 2002 noted that only 3.5% of those placed in sheltered work environments move on to competitive employment in any single year.

In the opening of the Americans with Disabilities Act (ADA) in 1990, Congress notes that society has had a tendency to segregate individuals in important areas such as employment and therefore states that “no covered entity shall discriminate against a qualified individual on the basis of disability in regard to job application procedures, the hiring, advancement, or discharge of employees, employee compensation, job training, and other terms, conditions, and privileges of employment” ([ada.gov](http://www.ada.gov), retrieved 2011). The passage of the ADA was to bring about a greater integration of individual with disabilities in the workplace. According to Blanck (2008), discrimination of individuals with disabilities has been reduced and more opportunities have opened.

Current Knowledge

Available statistics on employment by individuals with disabilities vary. However, the National

Survey of Americans with Disabilities (2010) reports that 21% of individuals with disabilities aged 18–64 had been employed with 59% of the general population maintaining employment. Data specific to individuals with autism spectrum disorders (ASD) are harder to find, but the information that is available suggests that those with ASD are less likely to be employed compared to other disability groups. In 2009, the National Longitudinal Transition Study 2 had found the following as it relates to individuals with autism spectrum disorder and employment (www.nlts2.org):

- 32.5% of young adults with autism spectrum disorders currently worked for pay versus an average of 59% of all respondents.
- 47.7% of youth with autism spectrum disorders had worked for pay in the past 2 years versus an average of 78.4% of all participants.
- 29% of young adults with autism spectrum disorders were looking for work if currently unemployed compared to 47.7% of all participants.

The study does not specify if those surveyed are in a competitive employment situation or not. However, it is important to note that individuals that are in competitive employment work a greater number of hours per week and earn more per week than individuals in noncompetitive employment (Schaller and Yank 2005).

Even though there is great benefit to the individual to be working in a competitive employment situation, only about 15% of individuals were doing so (Wehman et al. 2003). The rest were in a number of day habilitation services that were noncompetitive, and oftentimes, these individuals were not integrated with the community.

Current research indicates that individuals with ASD can work in a variety of community-based businesses. However, majority of individuals on the spectrum currently remain unemployed (Dew and Alan 2007).

Short Description or Definition

In the study of social cognition, the routes to understand others are subserved by separable, independent brain networks. Theory of mind (ToM) otherwise been referred to as "mentalizing" or "mind reading" constitutes one of the neuropsychological mechanisms, providing the understanding of someone else's thoughts or intentions. However, within this concept as a whole, have been identified distinct components of ToM accounting for the appreciation of the socio-affective and socio-cognitive information (Shamay-Tsoory et al. 2002; Hynes et al. 2006). Cognitive ToM reflects the understanding of someone's beliefs, while affective ToM requires the empathic appreciation of someone's emotional state.

Several mechanisms of atypical ToM are associated with autism spectrum disorders (ASD) (Cantio et al. 2016; Happé et al. 2017) converting its measurement into a clinically relevant feature that may explain and mitigate social difficulties in ASD population.

While subjects with autism present difficulties in standard ToM understanding, the majority of individuals with HFA/AS, whose intelligence ranges from normal to near-normal level and does not present language delay, are characterized by higher-order mind-reading abilities, often referred to as "advanced theory of mind."

Consequently, the conceptualization of the term "components of advanced theory of mind in autism spectrum disorder" refers to the assessment of subtle mentalizing difficulties within the autistic spectrum generated by distinct subdomains.

Historical Background

Autism Origins as a Distinct Diagnostic Entity

Only from 1980 and on, autism appeared for the first time as an independent classification in the DSM-3, published in 1980. Until that moment the concept of autism was encompassed in the core symptoms of schizophrenia. At this point, the perception of the condition changed from the description of a symptom to the description of a behavioral, developmental phenotype encompassing a range of symptoms in the social, communicative domain, as well as symptoms of rigidity and repetitiveness (Rapin 1997).

Clinical features, such as the presence of autistic traits in patients with schizophrenia (Kastner et al. 2015) and the development of schizophrenia in a significant proportion of children diagnosed with autism spectrum disorder (Larson et al. 2017), supported the connection between the two spectra at a clinical level in subsequent investigations, leading to numerous comparative studies (e.g., Ozguven et al. 2010; Lugnegard et al. 2013; Tin et al. 2017). However, beyond their similarities in certain features (Tin et al. 2017) to date, there is a clear-cut distinction in respect to neurocognitive profiles and separate diagnosis.

Currently, the umbrella term of ASD is used to describe all people diagnosed within the spectrum, including autism, pervasive developmental disorder not otherwise specified (PDD-NOS), and Asperger syndrome (AS) (APA 2013). Since the disturbances of social cognition are among the central characteristics of ASD, it has been considered as a disorder of the social brain, and it is nowadays categorized in the DSM-5/SCD as a communication disorder in the broader domain of neurodevelopmental disorders.

ASD and ToM Connection

As commonly described, the term theory of mind (ToM) refers to the ability of someone to understand another's thoughts, beliefs, and other internal states such as desires, emotions, or intentions (Frith and Frith 2006). The first application of the term in ASD research was in an experiment which used false belief paradigms to explore ToM in

children with autism (Baron-Cohen et al. 1985). To investigate this, they developed the Sally-Anne false belief task (Baron-Cohen et al. 1985; Wimmer and Perner 1983), in which Sally places an object in a box and leaves the scene. After this, Anne relocates the ball and Sally returns. Participants with well-developed ToM capacities succeeded in predicting Sally's behavior based on her false belief about the ball's location.

Since then a growing body of evidence on social cognition deficits has provided data consistent with the hypothesis that social difficulties in ASD are explained by a decreased ability to use mental state concepts to interpret and predict one's own and other people's behavior (Baron-Cohen et al. 2000; Tager-Flusberg 2007). This theoretical connection with ToM on social abilities remains highly correlated among recent literature. More specifically the two cognitive accounts of ASD that have received the most attention are ToM and executive function.

Likewise, the degree of ToM difficulties may vary widely depending on intelligence quotient (IQ) and language development defining particular ASD diagnosis, being more severe in autism than in Asperger syndrome (AS) or in high-functioning autism (HFA) (Baron-Cohen et al. 2000). Additionally, children diagnosed with ASD generally develop ToM later and continue to fail on these tests until late childhood and even adolescence (Happé 1995); therefore, age might be considered a positive correlate in healthy participants, but not in people diagnosed with ASD.

Current Knowledge

Advanced ToM

Traditionally, ToM is assessed throughout false belief understanding. These tasks relate to the understanding that different people can have different thoughts about the same situation. "First-order" false beliefs indicate what someone thinks about real events, while more advanced "second-order" false beliefs refer to what someone thinks about other people's thoughts. Thus, within the broad construct of ToM, advanced measures were created to examine adults' ability to reason about

mental states in more complex contexts including higher-order false belief understanding, emotion recognition, and social understanding (Livingston et al. 2018).

Impairments in advanced ToM tasks include the selection of subtle nonverbal social cues, interpretation of social stories, construction of social inferences, and comprehension of implied or non-literal meanings in the language (Baron-Cohen et al. 2001; Mathersul et al. 2013). Overall, conducting traditional or advanced ToM research in ASD individuals depends on the clinical expression in which impairments vary according to their age and the severity of their social and communicative difficulties.

In consideration of the diverse structure and performance, ToM may have overdevelopment, and measurements become more task-specific with age. While typically developed children between the ages of 3 and 4 years can solve verbally presented first-order false belief tasks (Wellman et al. 2001; Wimmer and Perner 1983), most children with ASD do not pass these tasks until the age of 11 years (Happé 1995). Then dealing with second-order false belief tasks can be solved by children around the age of 6 and 7 years, whereas advanced ToM abilities are required to process complex social situations in which the wrong behavior has to be represented by a cognitive and affective component, first appearing in typically developed children between the ages of 9 and 11 (Baron-Cohen et al. 1997). Preschoolers, middle childhood, and adults should, therefore, be examined with age-appropriate adaptations.

Distinct Theoretical Components of ToM

Since ToM origins as a concept of investigation, its study expanded to the identification of different aspects, grounded in a distinct neurobiological substrate, brain regions, and differing interacting functions. Understanding others' internal states may be a multidimensional process that interacts with other abilities, a process which may not occur in a single conceptual framework (Warnell and Redcay 2019). Tager-Flusberg and Sullivan (2000) had put forward "the componential view of theory of mind" which suggests the study of ToM as two differentiated processes: the social

cognitive, connected with what has traditionally been called theory of mind and is based on the conceptual understanding of the mind as a representational system, and then the social-perceptual or empathetic component, associated with the affective system and is based on the rapid "online" judgment of another individual's mental state from her/his facial expressions, gestures, tone of voice, movements, and actions.

Considerable research confirm over the years that affective and cognitive aspects of ToM are indeed somewhat separable involving overlapping but dissociable brain systems by highlighting the mediating role of ventromedial (VM) frontal lobes in ToM research (Shamay-Tsoory and Aharon-Peretz 2007; Hynes et al. 2006; Duval et al. 2011; Schaafsma et al. 2015). Depending on which ToM task is used and which aspect of ToM is focused on, research on ToM derived from autism has reported somewhat different results. The bulk of studies consistently support impairments in the general ToM performance of ASD individuals even in high-functioning adults with ASD (Cantio et al. 2016; Happé et al. 2017; Wellman et al. 2001; Ponnet et al. 2004). However, not all research argues for a ToM deficit as the key mechanism underlying the social interaction impairments seen in ASD (Stone and Gerrans 2006; Van de Cruys et al. 2014).

Recent evidence from behavioral data suggested that cognitive and affective ToM is differentially impaired in individuals with ASD. Some ASD literature supports findings for greater impairment in the socio-cognitive component of ToM (Rogers et al. 2007; Dziobek et al. 2008; Mazza et al. 2014) while others for the socio-affective ToM (Lockwood et al. 2013; Shamay-Tsoory et al. 2002). Understanding the way that cognitive and affective aspects of ToM relate to each other is complicated also due to the inconsistent and under-specified uses of relevant terminology. Some of these problems can be reconciled if ToM began to conceptualize as a multifactorial construct, comprised of multiple sub-processes.

Studying the effects of localized brain lesions constitute a set of trustworthy evidence. Comparative studies of the effects of localized brain

lesions suggest that there are some commonalities in the neural mechanisms of emotional processing and ToM. (Mitchell and Phillips 2015). In the past, decoding has often been conflated with emotional processing and reasoning with ToM. Nevertheless, this may not always be appropriate, since basic decoding mechanisms can specialize for either emotional information or intentional information, while other tasks require the perception and combination of both emotional and intentional information (e.g., when trying to decode sarcasm or deception; Adams Jr. and Kleck 2005). In this context, various theoretical models support that emotional perception always precedes ToM in the processing chain, while ToM cannot proceed without input from emotional perception (Baron-Cohen 2005; Mitchell 2006; Ochsner 2008). The fact that emotional process occurs at an earlier temporal stage compared to ToM (Corrigan 1997; Mitchell 2006) further supports the assumption that emotional processing and ToM are indeed related.

Along with the review conducted by Mitchell and Phillips (2015) collecting data from several lesion studies, it is suggested a possible overlap between emotional processing and ToM located in the medial PFC, probably in the right hemisphere. Moreover, neuroimaging data focus on studies that have compared the perception of affective cues against the inference of thoughts, intentions, and beliefs, indicating overlapping function between the substrates of emotional processing and ToM in dorsal PFC regions and at the temporal pole. In other researches have directly been compared the neuroanatomy of affective vs. cognitive ToM by manipulating experimental stimuli (e.g., “what are the characters thinking” vs. “what are they feeling”). Hynes et al. (2006) found a differential response in ventral prefrontal regions of the brain with affective ToM inducing greater activation of ventromedial PFC compared to non-affective ToM. A greater association between dorsolateral PFC activity and cognitive ToM was further supported by transcranial magnetic stimulation (TMS) data where suppression of right dorsolateral PFC activity has been shown to impair only cognitive ToM (Kalbe et al. 2010). In summary affective ToM (which bears some

resemblance to EP) and cognitive ToM partly share neural correlates but can also be differentiated. Therefore, overall research up to date theorizes that EP and ToM share some common components yet without excluding functional independence between the two processes in specific areas.

How Is Cognitive and Affective ToM Being Measured Up to Now?

In the last 15 years, several tests have been developed to tap higher-order mind-reading abilities, which are often referred to as “advanced theory of mind.” Numerous instruments have been proposed to assess ToM, or some aspect(s) of ToM, in individuals with ASD, although there is not yet a universally accepted operationalization of ToM. The more widely used instruments of this kind are “The Strange Stories Test” (Happé 1994), which contains written stories/scenarios with persuasion, white lies, double buffs, and deception; the “Faux Pas Test” (Stone et al. 1998), which involves the understanding of social situations where someone says something without considering the listener’s point of view, with negative consequences that the speaker never intended; and the “Reading the Mind in the Eyes Test” (RMET; Baron-Cohen et al. 2001), which involves recognizing a person’s mental state from the expression in their eyes.

A large number of studies continue to consider ToM a unitary construct, employing only one or two measures in order to capture ToM. Across a variety of specific tasks and modalities which have been argued to be important components of ToM (e.g., verbal versus nonverbal, deliberate versus automatic, implicit versus explicit), the distinction between affective and cognitive ToM captures the use of different cognitive abilities to solve these tasks. Both aspects of mentalizing considered critical predictors of well-being. Affective ToM is most often assessed by presenting either pictorial stimuli depicting complex affective states or verbal narratives that describe a protagonist’s emotion. The Reading the Mind in the Eyes Test reflects this former approach and is one of the most widely used and well-validated measures of this construct. Moreover, in the clinical assessment, it is also used

the Awareness of Social-Inference Test-Revised (TASIT; McDonald et al. 2006) a dynamic audio-visual-based assessment of social cognition. TASIT comprised of a series of 15–60 sec video vignettes and requires participants to implicitly encode and integrate contextual information in order to recognize emotions and determine the meaning and intention of speakers' dialogue, emotional expression, and other paralinguistic information. In respect to cognitive ToM, one of the best-validated methods of assessing this construct is via a comparison of true and false belief tasks. As mentioned before the Strange Stories and the Faux Pas Test tasks tap those domains and are well-validated measures that appear to have good sensitivity to social cognitive failures in clinical groups.

Recent research would ideally study these specific characteristics combining both cognitive and perceptual processes within the same test. In the Cambridge Mindreading (CAM) Face-Voice Battery (Golan et al. 2006) is required recognition of complex emotional mental states from dynamic faces, based on voice prosody and content of the spoken sentences. Recognition of complex emotional states is assumed to involve higher-level integration and mindreading but also low-level perceptual processes (Mitchell and Phillips 2015). Moreover, this test proves good discriminator validity between clinical (autism, Asperger syndrome) and nonclinical groups (Golan et al. 2006), and it is sensitive to developmental changes in ToM.

Novelties Measuring ToM

To date, a series of novel and previously overlooked approaches have been proposed in order to improve the measurement of ToM in research and clinical settings. Classic tests such as those described above "Strange Stories Test" and "Faux Pas Test" are considered "explicit" measures since ToM is prompted by direct mental state questions. Several findings suggest that individuals with ASD show relatively minor impairments on classical tasks (evaluated usually by explicit measurements) compared with their difficulties observed in clinical settings and everyday social situations (e.g., Lever and Geurts 2016;

Scheeren et al. 2013; Wilson et al. 2014). Clements and Perner (1994) were the first to empirically investigate a difference between implicit and explicit ToM; however, this distinction is currently debated (Carruthers 2017).

An implicit measure of social cognition is based on fast spontaneous, unconsciously, and inflexibly action, while explicit ToM reasoning is conquered around age 4 and allows for a deliberate consideration like the judgment of others' mental states. To this end, various studies (e.g., Apperly and Butterfill 2009; Sodian et al. 2014) support the notion of two ToM reasoning systems: an explicit system that verbally explains behavior based on mental states and an implicit system for spontaneous sensitivity to other's mental states. These differences in the representational repertoire of the two systems should thus manifest themselves in distinctive and differential patterns of performance.

Deschrijver et al. (2016) used implicit tasks to measure ToM suggesting that when ToM atypicalities are measured by response time on appropriate cognitive tasks, it may help to understand autistic symptoms in adulthood. Measuring and controlling reaction time (RT) have not been used systematically as a technique within classical ToM, while accuracy is considered as a ToM ability. Nevertheless, measuring accuracy alone can lead to misunderstandings when alternative cognitive strategies might compensate for ToM performance (Scheeren et al. 2013; Livingston et al. 2018). Furthermore, when participants are administered, such tests are given as much time as necessary to process the material, which may explain why individuals may pass the probe test yet still struggle in everyday situations. Thus, combining reaction time and accuracy data could further improve the efficacy of advanced ToM measurements.

Evidence from current studies measuring also implicit mentalizing such as spontaneous looking patterns that reflect intuitive tracking of another person's belief state, documenting clear difficulties in adults with ASD. Besides, recent neuroimaging studies (Kovács et al. 2014; Schneider et al. 2014) showed that tasks developed to measure implicit ToM engage brain areas that are core to

the explicit processing of other's beliefs, suggesting that social cognitive processes most likely underlie implicit ToM. Other recently developed tasks have sought to measure ToM by examining accuracy, via open-ended or multiple-choice questions, of mental state attribution after watching video clips of social situations (Brewer et al. 2017; Dziobek et al. 2008; Murray et al. 2017). The advantage of these tasks resides in the prerequisite of more than simple inferences from images or stories and consequently reflecting more realistic social situations.

Past measures of social cognition tended to focus exclusively on comprehension of a social situation (Mathersul et al. 2013), while recent research has begun to ask participants to generate possible social responses to typical interactions (e.g., "What would you do in this situation?"; Jameel et al. 2014) and found that autistic traits are associated with fewer pro-social responses (Murray et al. 2017).

Future Directions

A critical examination of limitations into existing ToM findings as well as the lack of convergence among conventional ToM measures will offer insight into cognition and behavior more broadly. Inconsistencies in the literature may account for various methodological differences across studies; however, recent work challenges to fill these gaps by understanding and controlling such limitations and further designing improved evaluation tools and theoretical contexts.

Briefly, among the most essential shortcomings, future research needs to disentangle is the variability in the tasks used to measure ToM. The administration of many instruments has not been standardized, and thereby reliable normative data are currently nonexistent. Another dearth emerges from past studies that did not adequately distinguish performance on tasks measuring distinct theoretical components of ToM. Future research needs to clarify theoretically as well as experimentally the extent to which the tasks make emotional and cognitive demands, which components

of ToM are most impacted in ASD, and whether distinct components of ToM predict symptom severity and social functioning in ASD.

Discrepancy also occurs between laboratory and naturalistic settings. Laboratory-based ToM tasks vary in their sensitivity to real-life task demand. For instance, Ponnet et al. (2008) and Chevallier et al. (2015) claim for real-life social contexts when measuring ToM as a parameter to capture the dynamics of social interactions. Deficits linked with ASD in interpreting emotional expressions are observed to be more pronounced when the context was naturalistic and unstructured rather than highly organized or predictable. Finally, the majority of ToM measures present information verbally, while fewer present information visually. Thereupon in many cases, ToM ability is underestimated due to verbal impairments, whereas individuals with good verbal skills pass ToM tasks that are mainly explicit in form presumably due to compensatory strategies.

CASL

Description

The CASL is an oral language assessment battery for individuals aged 3–21 years and is based on a comprehensive theory of language. Consisting of 15 tests, the CASL measures auditory comprehension, oral expression, and word retrieval processes in four linguistic categories: Lexical/Semantic, Syntactic, Supralinguistic, and Pragmatic. The CASL battery provides an in-depth evaluation of oral language processing systems, knowledge and use of grammatical structures, ability to use language requiring higher-level processing, and adaptation of language across contexts. The results of the CASL assessment provide value in measuring linguistic skill among children with language delays and disorders as well as the competence of individuals who are learning English as a second language.

Each of the 15 CASL tests is constructed differently and measures different aspects of oral language. First, the Lexical/Semantic tests assess knowledge and use of words and word combinations through five tests. *Comprehension of Basic Concepts* measures the ability of young children to comprehend words representing basic perceptual and conceptual relations. *Antonyms* assesses expression of a word that has the opposite meaning of a given word. *Synonyms* assesses the ability to identify a word with the same meaning as a given word. *Sentence Completion* measures the ability to retrieve and express one of the few appropriate words that fit the meaning of spoken

sentence. *Idiomatic Language* measures the expressive knowledge of a group of words that, when used together, have a conventional meaning different from the literal meaning of the individual words.

Next, there are five Syntactic tests that assess knowledge and use of grammar (morphology and syntax). *Syntax Construction* assesses the ability to generate sentences using a variety of morphosyntactic rules. *Paragraph Comprehension* measures the comprehension of syntax through a series of narratives spoken by the examiner. *Grammatical Morphemes* measures the metalinguistic knowledge of the form and meaning of the English language. *Sentence Comprehension* measures the ability to comprehend meaning of the syntactic-structure organization of sentences. *Grammaticality Judgment* assesses the ability to recognize and correct grammatical errors within sentences.

Then, four Supralinguistic tests measure comprehension of complex language in which the meaning is not directly available from lexical or grammatical information. *Nonliteral Language* measures the ability to comprehend figurative speech, indirect requests, and sarcasm. *Meaning from Context* measures inference ability that does not require the examinee to use world knowledge. *Inference* assesses the ability to integrate appropriate world knowledge that is not explicitly stated with information provided by the speaker. *Ambiguous Sentences* assesses the ability to comprehend multiple meanings given sentences containing elements that can be interpreted in more than one way. Finally, *Pragmatic Judgment* measures awareness of the appropriateness of language and ability to modify language in relation to the situation in which it is used.

The CASL is individually administered and requires no reading or writing on part of the examinee. Each test can stand alone, and each score can be reported as a standard score (mean of 100, standard deviation of 15, range of 40–160), percentile, normal curve equivalent (NCE), stanine, and test-age equivalent. These scores allow each test to be compared with every other test, both within a category and between

categories, as well as between tests of comprehension, expression, and retrieval. Additionally, a global measure of oral language can be calculated from a subset of representative tests to derive a CASL Core Composite. Examiners may also administer all of the tests appropriate for the child's age to use as a comprehensive battery. Depending on the students' age, Index Scores may be computed as representative measures of language categories (Lexical, Syntactic, Supralinguistic; available for ages 7–21) and processing (Expressive, Receptive; available for ages 7–10). Administration time varies based on the examinee's age and the number of tests administered. When administering the Core Battery tests only, it takes approximately 30 min to test children aged 3–5 years and 45 min to 1 h for older examinees.

The CASL has two record forms: Record Form 1 is appropriate for children 3–6 years, and Record Form 2 is for those 7–21 years. Three self-standing test easels contain all of the picture stimuli and item text, as well as administration and scoring procedures for each test. General testing information is provided in the easels as well, such as basal and ceiling criteria, allowance of item repetition if the examinee appears to not understand the task, and prompting guidelines for specific tests. Test easels are tabbed for each individual test, and starting pages are marked for the appropriate age ranges. The manual also provides procedural information, interpretation of the results specific to each of the 15 CASL tests, and technical properties such as the description of test development, standardization, reliability, and validity data. A separate Norms Book contains all the normative tables for the CASL in order to convert raw scores to standard scores and provides significance values for comparing differences between tests scores.

Historical Background

Originally published in 1999, the CASL was developed by author Dr. Elizabeth Carrow-Woolfolk as a comprehensive test of oral language based on her Integrative Language Theory, ILT (Carrow-Woolfolk 1988, 1994; Carrow-Woolfolk

and Lynch 1981). ILT combines and relates the linguistic, cognitive, and pragmatic aspects of language, which forms the basis for the classification of the CASL tests. In this view, a comprehensive understanding of language must take into account both the *meaning* of language and its *form*.

The content of language conveys meaning and is largely dependent on substantive words and word combinations. Words that refer to a relatively specific category of things are considered lexical morphemes (vocabulary). Throughout the CASL, the term “semantics” is used to describe the content of only the lexical morphemes of language. Conversely, language can be more abstract with a general meaning that refers to a wide range of things (pronouns, prepositions). These are considered grammatical morphemes (functors and inflections) which along with syntax (word order and structure of language) represent the form or structure of the language.

Language can be ambiguous when word constructions have multiple interpretations. Often an individual must use inference or contextual information to interpret an underlying nonliteral meaning of language. This type of nonliteral language is labeled supralinguistic, which implies that the interpretation of an utterance extends beyond the literal meaning and requires higher-level analysis to comprehend. This category of language emerges later in development and is an integral component in measuring linguistic skill during adolescence. Additionally, the relation of form and meaning is significantly influenced by context including social variables (setting, age, relationship), linguistic variables (type of discourse-conversation, a narrative, a lecture), and personal variables (intention, motivation, knowledge, and style of the sender). These contextual aspects of communication are considered pragmatic and can affect not only the manner in which language is expressed but also how it is interpreted.

The categorization of CASL tests follows the structure of the ILT. Lexical/Semantic tests address the meaning of language (Basic Concepts, Antonyms, Synonyms, Sentence Completion, Idioms). The Syntactic tests address meaning

derived from the structure of language (Syntax Construction, Paragraph Comprehension, Grammatical Morphemes, Sentence Comprehension, Grammaticality Judgment). The Supralinguistic tests measure understanding and use of complex meanings that require analysis above that of lexical and syntactic meaning (Nonliteral Language, Meaning from Context, Inference, Ambiguous Sentences). The Pragmatic test measures understanding of language that is dependent on context and social understanding (Pragmatic Judgment).

The theoretical distinction of these categories is reflected in the developmental literature as well. Children begin to use language at a lexical level and proceed to using two-word phrases and simple morphemes, such as prepositions. Gradually, utterances lengthen by the addition of complex morphemes and the use of structurally advanced syntax, such as noun and verb agreement. Eventually children can adapt their language to the needs and demands of the environment. Only then do children begin to comprehend and express nonliteral language and idioms. Comprehension and expression of complex language in which the utterance units rely on one another for meaning evolves gradually, once the use of basic elements has matured.

The CASL procedures and content reflect the two distinct dimensions of language: knowledge (structure, form, and content of language) and performance (internal systems used to comprehend and express language). As a result, the CASL separates listening comprehension (Receptive Index) from oral expression (Expressive Index). Although these two major processes of language have common elements (e.g., they both draw upon the same basic knowledge of language structure and meaning), there is empirical evidence for their distinction (Carrow-Woolfolk 1985).

Psychometric Data

In developing the CASL, Dr. Woolfolk created items that would elicit information not only about an individual's language knowledge and competency but the individual's use of language and functionality of communication as well.

Initial items were piloted in 1992, and normative data were collected between 1996 and 1997. The CASL was normed on a nationwide standardization sample of 1,700 individuals, 3–21 years, which matched the most current US Census data (1994 Current Population Survey) on gender, race/ethnicity, region, and mother's educational level. Additionally, CASL sampling procedures drew children from public and private schools without respect to special education status. As a result, children receiving various special education services were represented in the normative sample in approximately the same proportions that occur in the US school population. The following five major special education categories were included: Specific Learning Disability (3.4% of CASL sample), Speech or Language Impairments (1.5%), Mental Retardation (0.6%), Emotional Disturbance (0.3%), and Other Impairments (0.4%).

The CASL tests, Index Scores, and Core Composites have high internal consistency and test-retest reliabilities. Item analyses, including Rasch scaling methods, were utilized to obtain the final test items. For each age band (12 groups), all of the Core Composite reliabilities are in the .90s, and the indexes range from .85 to .96. Test-retest reliability was assessed by administering the CASL twice (median 6 week interval) to 148 randomly selected examinees in three age groups: 5–10 to 6–11 (41 cases), 8–10 to 10–11 (38 cases), and 14–16 to 16–17 (69 cases). Results suggest only a minor practice effect and provide strong evidence of the stability of CASL scores.

Five criterion-related validity studies and eight clinical validity studies were conducted during standardization, with over 600 participants. In the first group of studies, CASL scores were compared with four measures of oral language (Test for Auditory Comprehension of Language-Revised [TACL-R]; Listening Comprehension and Oral Expression Scales of the Oral and Written Language Scales [OWLS]; Peabody Picture Vocabulary Test, Third Edition [PPVT-III]; Expressive Vocabulary Test [EVT]) and a measure of cognitive ability (Kaufman Brief Intelligence Test [K-BIT]). The highest overall correlations are with the OWLS, which assesses

the same four linguistic categories as the CASL. While the OWLS assessment has a wide-range approach, the CASL allows for an in-depth study of specific skills. For the clinical validity studies, performance of eight different clinical groups was examined: Speech Impairment, Language Delay, Language Impairment, Mental Retardation, Learning Disability (Reading), Learning Disability (Undifferentiated), Emotional Disturbance, and Hearing Impairment. Each clinical case was matched with a case from the standardization sample on the following variables: age, gender, race/ethnicity, and SES as measured by the mother's education level. Children in the matched control groups were not receiving any special services. The manual includes tables reporting the mean and standard deviation of each clinical group and the matched control groups as well as the significance value of the difference between groups.

In general, the clinical group scored about the same as the control group on most of the CASL tests for the Speech Impairment group. In contrast, the Language Delay, Language Impairment, Emotional Disturbance, and both Learning Disability groups scored significantly lower than their matched control groups. Adolescents with mild mental retardation scored approximately two standard deviations below the mean on all CASL tests. For Hearing Impairment, the clinical group scored lower on all CASL tests (e.g., about one standard deviation below the mean); however, interpretation is limited due to a small sample size for this group.

Clinical Uses

The CASL can assist speech/language pathologists, psychologists, educational diagnosticians, early childhood specialists, and other professionals in measuring oral language processing skills and knowledge in preschoolers through young adults. The age-based norms are useful in identifying language impairments to meet the requirements of Public Law 94-142 (now incorporated into the Individuals with Disabilities Education Act [IDEA] reauthorized as Public

Law 105-17). Further, CASL standard scores can be directly compared with many other tests when using the available standard scores based on the common metric scale (mean of 100, standard deviation of 15).

The CASL assists clinicians in understanding the relation between an individual's score and any delays or disorders in language. The presence of poor performance in one or more of the language categories may be indicative of a language disorder. Further, a significant discrepancy in performance among the categories may indicate a problem. For example, comparisons can be made between receptive and expressive tasks or between tasks highly dependent on retrieval and those that are not. In-depth qualitative information from the CASL may also be used to identify the possibility of a disorder even though the quantitative level of performance is not atypical. Clinicians are also able to create a profile of an examinee's oral language strengths and weaknesses across distinct categories of language. The CASL can also provide a record of growth in language skills and knowledge across a broad time span (3–21 years) through using the same instrument.

Communication deficits are often associated with autism spectrum disorders (ASD). The CASL can provide clinicians with in-depth information about an individual's knowledge and use of language, which may help to identify problem areas associated with ASD. For example, the CASL can be used to identify deficits in expressive compared to receptive language as well as problems in the *use* of language (e.g., pragmatics) as opposed to the *content* or *form* of language (lexical/semantic and syntactic). This may be particularly useful for high-functioning ASD individuals who often have advanced lexical/semantic knowledge and syntactic skills, but relatively poor pragmatic skills associated with difficulties in social interaction (Paul and Wilson 2009). Recent evidence suggests that the Pragmatic and Supralinguistic areas of the CASL are useful particularly in documenting the difficulties that individuals with ASD have in communicating flexibly across contexts (Reichow et al. 2008).

Comprehensive Transition Program

Paul K. Cavanagh
Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA

Definition

A Comprehensive Transition and Postsecondary Program is a college-based program for students with an intellectual disability defined and created by the enacting of Public Law 110–135: the Higher Education Opportunities Act (HEOA, 2008). As defined in the law, a Comprehensive Transition and Postsecondary Program is “designed to support students with intellectual disabilities who are seeking to continue academic, career and technical, and independent living instruction at an institution of higher education in order to prepare for gainful employment” (HEOA, sec. 760). Such a program must be

offered by an institution of higher education and have an advising and curriculum structure. The curriculum must provide for the students with an intellectual disability to spend at least one-half of their time on academic components with non-disabled individuals.

A Comprehensive Transition and Postsecondary Program is a program based at a college or technical school to assist students with an intellectual disability, transitioning out of secondary education, who are not yet ready to enter the workforce or to enroll full-time in a college or technical school. The programs are designed to provide the necessary instruction and support in social functioning and independent living skills to enable the student to prepare for gainful employment.

Institutions of higher education must apply to the United States Department of Education in order to have their program approved as a Comprehensive Transition and Postsecondary Program. In order to be eligible to apply for approval, the institution of higher education must already be approved to administer Federal Financial Aid for its students. A student enrolled in an approved Comprehensive Transition and Postsecondary Program is eligible for Federal financial assistance under the Federal Pell Grant, Federal Supplemental Education Opportunity Grants (FSEOG), and Federal Work Study (FWS) programs. As opposed to the general requirements for a postsecondary student to be eligible for federal financial aid, a student with an intellectual disability in an approved transition program does not have to be enrolled for the purpose of obtaining a degree or certificate and the student is not required to have a high school diploma, a recognized equivalent of a high school diploma, or have passed an ability to benefit test. However, the student must be making satisfactory progress according to the institution’s published standards for students enrolled in its comprehensive transition and postsecondary programs (34 CFR, § 668.233).

Computed Tomography

Kevin A. Pelphrey Harris
Child Study Center, Yale University School of
Medicine, New Haven, CT, USA

Synonyms

[Computed axial tomography \(CAT\)](#); [CT](#); [X-ray computed tomography](#)

Definition

Computed tomography is a medical imaging method employing tomography created by computer processing of X-ray images. A form of digital geometry processing is used to generate a three-dimensional image of the inside of an object from a large series of two-dimensional X-ray images taken around an axis of rotation. This

volume of data can then be manipulated via computer algorithm to observe and measure bodily structures (including brain structures) based on their ability to block the X-ray beam. This was one of the first techniques available to neuroscientists to study the structure of the living human brain. As such, it was one of the first techniques to be used to study brain structure in individuals with autism providing some of the earliest insights into the neural systems affected by autism.

Computer-Assisted Instruction to Teach Academic Skills

Jenny R. Root¹, Bradley Stevenson² and
Luann Ley Davis³

¹School of Teacher Education, College of
Education, Florida State University, Tallahassee,
FL, USA

²University of North Carolina Charlotte,
Charlotte, NC, USA

³University of Memphis, Memphis, TN, USA

Definition

Computer-assisted instruction (CAI) has been defined as a systematic approach to developing students' knowledge and/or skills that uses a

computer as a central feature to support instruction via activities including, but not limited to, presenting materials, assessing progress, and guiding activities (Anohina 2005). CAI is a subset of technology-aided instruction, and is distinct from online, Internet, or other network learning in that CAI implies the software is local to the computer, not accessed via the Internet.

Historical Background

Technology has transformed everyday life for many people in the twenty-first century. From its infancy in the form of teaching machines (Pressey 1926; Skinner 1958) to the wide forms and platforms that are ever evolving (Stephenson and Limbrick 2015), instructors and researchers have evaluated the usefulness of technology as the central feature of an intervention to increase academic skills. The current application of CAI originates from the work of psychologists in the early twentieth century.

Sidney Pressey was the first to experiment with teaching machines. He defined the teaching machine as an automatic or self-controlling device that presented a unit of information, provided some means for the learner to respond to the information, and provided feedback about the correctness of the learner's responses (Pressey 1926). Approximately 30 years later, B. F. Skinner (1958) published descriptions of his own teaching machines, which were capable of requiring constructed responses. Skinner attributed the lack of professional enthusiasm and adoption of Pressey's machines to cultural inertia, in that there was not a need for instruction to be automated when there was an abundance of teachers. However, there was an increased interest in teaching machines in the 1950s and 1960s when the baby boom led to a shortage of teachers. The promise of teaching machines was that they provided a solution to the problem of insufficient teacher attention to address all students varying needs. It was presumed that the teaching machine could replace some functions the teacher was currently providing. There were, however, criticisms of teaching machines in the late 1960s, including being

unnecessary for presentation of programmed materials, being too expensive, and individuals' doubts about the extent to which the teaching machines could teach (Benjamin 1988).

The teaching machines developed by Skinner and others, such as the *AutoTutor* (Crowder 1962), were based on the principles of programmed instruction (Molenda 2008). Programmed instruction was described by Bijou et al. (1966) as the process of systematically and effectively arranging and rearranging an environment to elicit a change in a targeted behavior. The intent of programmed instruction is to make the teaching-learning process effective and customized to meet individual needs (Molenda 2008). Skinner's early work in programmed instruction focused on content that was arranged in small chunks of information that built upon each other. In a forward-chaining procedure, the student did not progress forward to a new "chunk" of information until the previous had been mastered. In this form of programmed instruction, learners progressed at an individual pace. The use of reinforcement in the form of knowledge of a correct response increased the likelihood of future correct responding. Programmed instruction was incorporated into textbooks as well, relieving the necessity for hardware. Research using teaching machines to deliver programmed instruction led Skinner to refer to the use the term *technology of teaching* (Skinner 1968).

The evidence-base of CAI to teach academics to students with autism spectrum disorders (ASD) goes back over three decades. Panyan (1984) was one of the first to make the argument for the incorporation of computers into the education of students with disabilities in her review of literature on the use of computers with individuals with ASD. She concluded her review by proposing several distinct benefits computers may offer. These included consistency of instruction, the potential to facilitate generalization, and the inclusion of preferred sensory stimuli into instruction.

As technology has rapidly changed in format and capabilities since Panyan's initial review, the field of special education has followed with empirical evaluations on how this may enhance the lives of individuals with ASD. Because

educators of students with ASD are responsible for providing access to and ensuring progress in the general curriculum (Browder et al. 2007), a specific focus has been on how to effectively use technology to teach academics to students with ASD. Empirical investigations and periodic reviews of research are critical to fulfilling this responsibility because they identify which uses of technology are actually effective, and when educators use practices that are supported by scientific evidence, student outcomes improve (Cook et al. 2008, 2012).

Current Knowledge

In the first literature review on the use of CAI to teach academics to students with ASD, Pennington (2010) found 15 articles that (a) were published in a peer-reviewed journal between the years of 1998 and 2008, (b) were based on experimental research, (c) manipulated an independent variable involving the use of CAI, and (d) collected data related to an academic skill. All of the studies that met inclusion criteria addressed literacy skills. Pennington found a total of 15 articles that met inclusion criteria, and concluded that CAI was effective for a limited number of skills, namely literacy skills, but that many of the designs lacked experimental control.

Knight et al. (2013) had similar findings with 25 out of 25 included studies teaching literacy skills. Inclusion criteria for Knight et al. (2013) consisted of the following: (a) published in a peer reviewed journal between 1973 and 2012, (b) teaching an academic skill, and (c) inclusion of technology as the intervention or a part of the intervention package, including video modeling. Knight et al. (2013) found a total of 25 articles that met these criteria, the majority of which targeted literacy skills. However, the quality was limited as most of the studies met only a few quality indicators (QIs) for single-subject or group design as outlined by Horner et al. (2005).

An updated review by Root et al. (2017) included 29 studies that (a) were published in a peer reviewed journal between 1995 and May 2015, (b) included at least one participant with

ASD, (c) used a recognized experimental or quasi-experimental design, (d) had a dependent variable that measured an academic skill, and (e) CAI served as a key component of the independent variable, excluding video modeling. Authors coded each study for QIs using guidelines of the National Technical Assistance Center on Transition (NTACT 2016). These guidelines provided operational definitions for the QIs outlined for single-case research by Horner et al. (2005) and group experimental research by Gersten et al. (2005). After coding each study for QIs, authors evaluated the evidence to determine if CAI to teach academics to students with ASD was an EBP. Of the 29 studies that met inclusion criteria, 24 used single-case methods. Of those 24, two met criteria for high quality studies and an additional eight met criteria for acceptable quality, therefore satisfying criteria for classification as an EBP. Of the five group experimental studies, two met criteria for high quality, further meeting the NTACT requirements for classification as an EBP.

After determining that CAI was an EBP for teaching academics to students with ASD, Root et al. (2017) further analyzed high and adequate quality studies included in their review for instructional variables to provide a more descriptive picture of the evidence base in terms of content, context, and instructional materials and methods. Nine out of 12 high and acceptable quality studies targeted literacy skills, meaning the evidence for teaching nonliteracy skills (e.g., math, science, and social studies) is not high. The context of CAI was primarily the special education classroom, with other settings included a clinic, conference room, computer lab, and a participant's home. A total of 94 participants with ASD were included in high or adequate quality studies, the majority of whom were male (78%). Unfortunately, only five studies reported ethnicity, making inferences into the generalization of findings according to ethnicity impossible.

The instructional materials used in the high and adequate quality studies included desktops, tablets, and laptops. Interventions were delivered through software or applications in the majority of the studies. Every study used behavioral

instructional methods, aligning with the origin of CAI in Skinner's teaching machines and what is known about the effectiveness of systematic instruction to teach students with ASD.

With the establishment of CAI to teach academics to students with ASD as an EBP, practitioners should consider ways CAI can be incorporated into instruction to overcome barriers to skill acquisition or give students access to academic content. This implication is especially relevant for literacy, as the majority of the evidence to support CAI targets literacy skills. In addition to efficacy, incorporating CAI into instruction can have several other benefits. For instance, the electronic format of many CAI interventions easily facilitates creation, presentation, and transfer of learning materials more feasible for practitioners. This may enable sharing among educators and families, allowing for continuity of interventions across classrooms, school years, and between home and school. In addition, CAI allows for modification to learning materials based on individual student needs (Knight et al. 2013). For example, although one PowerPoint or SMARTboard lesson may be created to address a common learning objective, it can be individualized to address students' interest topics, prerequisite skills, or to adjust for low- or high-ability learners. CAI is not intended to replace teacher instruction; rather, it may supplement or enhance teacher-directed instruction. It may increase the efficiency of instruction by reducing the amount of intensity of teaching monitoring required (Knight et al. 2013). This would allow for teachers to target multiple students' objectives within one lesson.

Future Directions

CAI practices are constantly evolving, and as a result educators may find it challenging to keep pace. Classrooms no longer maintain previous staple items such as chalkboards and overhead projectors, which have given way to items such as SMARTboards and portable tablets. This new technology and the practices associated with them reflect an expansion of the definition of

technology interventions for students with ASD (Wong et al. 2015). Additionally, assistive technology tools, devices, software, and services are increasingly interwoven into the fabric of all settings (e.g., general education, resource, separate), changing the dynamics of today's classrooms. As such, additional research is needed to keep pace with the rapid advances in technology.

First, research into content areas beyond literacy remains a need for students with ASD, as nonliteracy areas can have meaningful impact on students' postsecondary success (Wei et al. 2017). Students with disabilities, including students with ASD, are increasingly being included within the general education classroom for all subject areas. As a result, it is important for future experimental studies to target core content academic skills such as inquiry-based science, and mathematical problem-solving. Current technology can be used to modify content for accessibility, to align content to state standards, and to address the individual needs of students with ASD.

Second, the majority of the research has taken place within separate settings. More and more students with ASD are being educated within less restrictive settings, and CAI can serve as the catalyst to provide access to general education for students with ASD. Therefore, it is important for the context of research to expand beyond the special education classroom and investigate the effects of CAI to teach academics to students with ASD within general education settings as well. Future research should include treatment packages that look to academics for students with ASD through the use of combining CAI and behavior analytic approaches to instruction.

Third, the results of the analysis of instructional materials and methods of high and adequate quality studies may be of interest in future research using CAI. Instructional materials are no longer limited to consumable worksheets; they now include devices, software, assistive technology tools and services to deliver CAI to students with ASD. Looking to future trends in CAI, some of the technology listed should be considered for future research:

1. **Websites:** Although there are many websites available for teachers to use in academic instruction, there is limited experimental support (Bouck et al. 2014). As a result, expanded research using materials available on the Internet is warranted.
2. **Mobile devices** (cell phones): What was once “smart” is now “cognitive.” Smart devices such as meters, lighting, or machines evolve with artificial intelligence enhancements that provide more sensory, context-aware, and complex capabilities. Cognitive technology is modeled on the human brain and has potential to have self-learning abilities. As our mobile devices evolve, research must keep pace with the effects of these devices on student academic progress and how they can best be used within educational environments.
3. **Projection apps:** First introduced for mobile devices, projection apps now work specifically with portable tablets to increase engagement and collaboration. The projection app will allow teachers and students to wirelessly display content from portable tablets on attached projectors. Using the app’s Moderator function, educators can create a collaborative classroom by displaying up to four different portable devices simultaneously, with a maximum of 50 devices connected. Using the app, students and educators also can connect to mobile devices anywhere with wireless connection, making it useful for a one-to-one classroom context. Research is warranted on how to do this effectively.
4. **Virtual reality (VR):** VR is beginning to be used in business communications, retail, entertainment, sports, health, and other industries. Makers of VR have claimed that VR has the potential to completely change how we work, shop, play, and consume media. Future research should include using VR to teach academics to students with and without ASD.
5. **Voice control to sentient:** Voice control software has moved from simply voice-to-text to now include such skills as Internet searches, making phone calls, turning lights on/off, and interfacing with devices that are embedded into our environment (e.g., mobile devices).

Sentient tools are aware of their context, environment, and social interactions. As technologies such as cloud-based artificial intelligence, collaborative robots, and ever-more sophisticated machine-learning algorithms begin to converge, we will start to see the emergence of these capabilities in smart cars, homes, manufacturing, and education. Thus, research is needed for how to use this technology to improve education for students with ASD.

6. **Artificial intelligence personal assistants, chatbots, and conversational interfaces:** Advances in machine learning and natural language processing have already made conversational mediators possible. As they grow in sophistication, they look to move from the fringe and become a primary interface for Internet of Things devices and networks. Research is warranted on how the use of AI can enhance or impede educational and functional skills for students with and without ASD.

These are only a few examples of the multitude of ways CAI instructional materials for students with ASD have made their way into classrooms. Looking to future trends, it is important for educators to continue to investigate all the various assistive technology tools, devices, and services to determine their effectiveness, efficiency, and evidence-base. Finally, future experimental research should adhere to established design QIs. For future studies to be able to contribute to the evidence base, they need to attend to QIs such as those described by Gersten et al. (2005) and Horner et al. (2005).

Computer-Based Intervention Assistive Technology

Vannesa T. Mueller

Speech-Language Pathology Program, University of Texas at El Paso College of Health Science, El Paso, TX, USA

Definition

Computer-based interventions are those that use technology in some form to provide an interactive, multisensory learning experience. Also called computer-assisted instruction (CAI), this form of intervention is used to present information, allow a user to practice certain skills repeatedly, or to test knowledge or comprehension.

Historical Background

Computers have been used with individuals with autism since the 1970s. Colby (1973) used a computer and keyboard to increase the spontaneous verbalizations of children with autism. It was the

intent of the researcher to allow the children to engage in free play with the computer system that was designed to say the names of the letters the children typed or provide some kind of visual reinforcer when a letter was typed. Thirteen out of the 17 participants in the study showed increased language after the therapy. Throughout the rest of the 1970s and early 1980s, most of the evidence that was published regarding computer-based technology was anecdotal and not systematic. These interventions focused on learning a computer language (Goldenberg 1979), playing a computer game (Frost 1981), responsiveness (Geoffrion and Goldenberg 1981), attention (Pleinis and Romanczyk 1983), and social skills (Panyan et al. 1984).

By the mid 1990s, approximately 45 commercially available software programs were marketed for children and young adults with autism. These programs were created by a small number of developers to target cause and effect and language and cognitive development. Higgins and Boone (1996) described best practices for the creation of software for individuals with autism. The authors noted that the symptoms of autism manifest differently in each individual, so they encouraged educators and others working with students with autism to create their own computer-based interventions to implement specific strategies that are known to work with the students. Eighteen software guidelines were provided for those who wished to create software for children with autism. The guidelines cover many aspects of software design such as age appropriateness and principles of repeated practice. Additionally, Higgins and Boone (1996) provided tips and strategies related to creating software for children with autism.

Recently, the field of computer-based interventions has seen a steady growth in the quantity and creativity applied to this population. Virtual reality technology has been utilized to address social difficulties and pragmatic impairments typically seen in individuals with autism (Self et al. 2007), an electronic tutor has been developed to aid in vocabulary development (Bosseler and Massaro 2003), and robots have been created to target social interactions and joint attention (Robins

et al. 2005; Robins et al. 2004). Additionally, with the fervor over the Apple iPod touch, iPad, and approximately 350,000 apps that are available, much attention and speculation has been focused on the use of this new technology. GeekSLP.com is a blog designed for speech-language pathologists focused on technology use. There is also a GeekSLP app available for the iPad which helps identify apps that are appropriate for use by speech-language pathologists in the clinical setting.

Rationale or Underlying Theory

What human beings lack in patience, predictability, and consistency computers make up for. Microcomputers were introduced in the interventions of children with autism due to the finding that children with autism spent a large amount of time playing with machines compared to playing with human beings (Colby 1973). Computer-based interventions have the ability to control where and how stimuli are presented to help children with autism compensate for attentional difficulties and problems with filtering tangential or unnecessary information. Difficulty with unpredictability is a common symptom of autism. Computer-based instruction can vary a routine or program in very small increments, helping an individual with autism to accept these changes and build tolerance for change. See Panyan (1984) for a discussion on the early rationale for computer-based instruction for children with autism. More recently, Blischak and Schlosser (2003) have argued that computer-based interventions can contribute in unique ways to the services provided to individuals with autism due to the cognitive styles and learning preferences of the population.

Goals and Objectives

The goals of computer-based intervention are as varied as the purposes for them. Recently, a computer-based intervention can be found for nearly every area of difficulty afflicting

individuals with autism from vocabulary to attention to pragmatic abilities. The ultimate goal for these programs could be generalization of the skills learned to the individuals' natural environment. However, some programs aim at allowing the individual user practice at a certain skill. In this case, the software is a tool to be used as part of a rehabilitation package. It is the responsibility of the intervener to help the individual with autism to generalize the skills learned and practiced.

Treatment Participants

Due to their versatility, ability to be individualized, and recent availability (related to smaller size and lower price), computers and technology are being used to a much greater extent today than ever before. Technology is a mainstay of the general education curriculum as well as the special education curriculum. Because of this, computer-based interventions could be appropriate for any individual.

Treatment Procedures

The specific procedures vary by the computer-based intervention. Due to the variety of programs available and the myriad of difficulties they target, generalizations regarding treatment procedures cannot be made.

Efficacy Information

Computers have been used successfully in interventions with individuals with autism (Chen and Bernard-Opitz 1993; Colby 1973; Higgins and Boone 1996). Computers are predictable, cueing can be systematically removed to promote independence in a skill, and an individual can practice skills in an environment which is nonjudgmental. These factors have increased the likelihood of the success of an intervention which utilizes some kind of computer-based intervention. The outcome of research that compares computer-based intervention with teacher-based intervention

favors computer-based intervention (Bernard-Opitz et al. 1990). Compared with traditional instruction, children with autism have been shown to attempt more responses, answer more questions correctly, and had improved behavior and developed better literacy skills with a treatment that consisted of computer-based instruction (Chen and Bernard-Opitz 1993; Heimann et al. 1995).

An underlying question in the above studies pertained to generalization. Can an individual with autism transfer the skills learned from a computer-based intervention to real life? A computer-based intervention used by Hertzroni and Tannous (2004) was shown to generalize to the children's natural classroom environment. After children with autism were exposed to the computer-based intervention that focused on the use of relevant utterances and reduction of the amount of echolalic utterances, the children produced more relevant speech and reduced the number of immediate echolalic utterances (Hertzroni and Tannous 2004). A review of computer-based intervention was recently published by Pennington (2010). In that review, the results of 15 studies showed that targeted academic skills were acquired by the participants with autism spectrum disorders. Pennington (2010) concludes that computer-based instruction is a promising area of intervention for this population.

Outcome Measurement

Generalization of the target skills acquired from computer-based intervention to a naturalistic setting is what should be measured as the outcomes of this type of intervention. Although it is important for individuals to be able to acquire and practice skills in the relative safety of a computer program, it is more important for them to be able to use the skills in their everyday lives.

Qualifications of Treatment Providers

Many of the commercially available computer-based intervention software packages are easy to

install and, their use is fairly intuitive. However, for the computer-based intervention to truly have an impact on the language or cognitive skills of an individual with autism, a trained interventionist should prescribe their use and oversee the effectiveness of the tool. Speech-language pathologists, occupational therapists, special educators, and autism specialists are all trained in the use of these types of tools and can help with knowing which computer-based interventions would be most appropriate. These interventionists can also help with monitoring the outcomes of the intervention and will know how quickly cues and prompts can be faded to result in the most efficient and effective treatment.

Conduct Disorder

Ricardo Canal-Bedia

Clinical Psychology Department, Department of Personality, Assessment, and Psychological Treatment, Centro de Atención Integral al Autismo (INFOAUTISMO), University Institute of Community Integration (INICO), University of Salamanca, Salamanca, Spain

Synonyms

Behavioral disorder; Challenging behavior; Disruptive behavior; Dissocial behavior; Problem behavior

Short Description or Definition

Conduct disorder (CD) is a behavioral disturbance occurring in childhood and adolescence characterized by a persistent and repetitive pattern of behavior that violates the basic rights of others or major age-appropriate societal rules. CD involves a number of problematic behaviors, including oppositional and defiant behaviors, and antisocial activities (e.g., lying, stealing, running away from home, truancy, physical aggression, and coercive behaviors).

People with autism spectrum disorder (ASD) may have several problematic behaviors that are also found in people with CD, such as hyperactivity, impulsivity, aggression, and difficulty with following directions or being cooperative, and both conditions may share other features such as deficit in attributing mental states, poor verbal abilities for describing affective states, or reduced pragmatic skills. It is, however, rare that both conditions occur together (i.e., as comorbid conditions) (Simonoff et al. 2008). While presenting problematic behavior in individuals with CD is considered to arise from abnormal learning, problematic behavior of individuals with ASD can be explained by their difficulties in developing social and communicative skills.

Categorization

CD is classified in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) (American Psychiatric Association [APA] 2013) within the Disruptive, Impulse-Control, and Conduct Disorders group, which also includes Oppositional Defiant Disorder (ODD), Intermittent Explosive Disorder (IED), Antisocial Personality Disorder (APD), Pyromania, Kleptomania, and Other specified or unspecified disruptive, impulse control, and conduct disorders. Because all they share problems with emotional and behavioral self-control, this new group brings together disorders previously described in the chapter Disorders usually first diagnosed in infancy, childhood, or adolescents and in the chapter Impulse control disorders not otherwise specified (see Fig. 1). However, the International Statistical Classification of Diseases (ICD-10) (World Health Organization [WHO] 1992) categorizes the ODD as a particular form of CD, usually occurring in younger children, primarily characterized by markedly defiant, disobedient, disruptive behavior that does not include delinquent acts, or the more extreme forms of problem behavior. On the other hand, dimensional classification systems, based on studies of factor analysis to cluster specific behavioral symptoms, place both disorders within the group of externalizing disorders (Achenbach and Rescorla 2001).

There are several reasons for classifying CD and ODD as two different categories of disorders. First, age of onset for ODD (usually before age 8) is always at an earlier age than the onset of CD, which can have a childhood onset (if at least one symptom is present before 10 years old) or an adolescent onset (if no behavioral problems occur before the age 10). The second reason is that only a small group of children with ODD will develop CD at later ages. Finally, the third reason is that, although both disorders share behavioral characteristics of aggressiveness, aggressive behaviors are qualitatively different for each type of disorder. This distinction has been demonstrated by Frick et al. (1993) who showed that CD and ODD can be differentiated from a dimensional point of view. They conducted a meta-analysis with 60 factors

Conduct Disorder, Fig. 1 Classification of conduct disorder according to DSM-5 (APA 2013) and ICD-10 (WHO 1992)

identifying two bipolar dimensions: “destructive-nondestructive” behaviors and “overt-covert” behaviors. They concluded that most conduct problems could be classified within these two orthogonal dimensions. The overt-nondestructive cluster reflected the criteria for ODD, whereas the other three clusters, with features more indicative of property and status violations, represented CD symptoms (see Fig. 2).

For diagnosis of CD, the individual must have presented in the past 12 months “a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated” (APA 2013). Behaviors that must be present fall into the following four categories of aggressive behavior:

1. Aggressive acts toward people or animals
2. Destruction of property
3. Deceit or theft
4. Violation of rules

At least one of the above criteria must have been presented during the last 6 months. Moreover, the disturbance in behavior must cause clinically significant impairment in social, academic, or occupational functioning.

The age of onset determines the type of CD (see Fig. 1), and the severity depends on the damage caused to others. The behaviors that characterize a mild severity include lying, truancy, and running away at night without permission. Moderate severity may include acts of vandalism and

Conduct Disorder,

Fig. 2 Classification of disruptive behaviors (Adapted from Frick et al. 1993)

theft without confrontation. Severe cases include forced sex, physical cruelty, and use of a weapon and breaking and entering.

Recent studies indicate that a significant proportion of children with ASD may also be characterized with ODD symptoms. For example, two recent studies found that the percentage of children with ASD who meet DSM-IV criteria for ODD is 13% in the age group of 3–5 years and 27% in the age group of 6–12 years according to parental ratings, and when rates from teachers were considered, the numbers were 21% and 25%, respectively (Gadow et al. 2004, 2005).

Problem behaviors that are most often identified in individuals with ASD are physical aggression, self-injury, destruction of property, arguing nature, temper tantrums, and disruption. But other behaviors, such as explosive behavior, running away, stubbornness, violation of rules, defiant, threatening, or not to accept being guilty, have also been identified as moderate or severe conduct problems in people with ASD (Lecavalier 2006). Individuals with ASD present more problem behaviors than typically developing children, and overall levels of problem behavior are positively correlated with severity of ASD (Matson

et al. 2009). About one third of individuals with intellectual disability (ID) who exhibit problem behavior have comorbid diagnosis of ASD (Myrbakk and von Tetzchner 2008), and the more severe the ID, the greater the risk of problem behavior (Holden and Gitlesen 2006).

A common way of categorizing problem behaviors in people with ASD is based on the function of these behaviors in their natural context, but there are no systematic reviews about the possible functions that may play a role. In addition, a behavior problem may have more than one function. The most common functions that can be found in the literature are attention-seeking, avoiding, tangible benefit, or being alone (i.e., nonsocial, self-stimulatory, or automatic reinforcement). Avoiding pain or discomfort has also been described as a possible function of problem behavior.

Epidemiology

Rates of prevalence estimates of CD vary widely depending on the methodology used in each study and on the ascertainment procedures. The disorder

is considered to be a common mental health problem in children and adolescents and appears to have increased in the recent years. CD may be higher in urban than in rural areas and appears more often in boys than girls. Prevalence rates for the disorder in childhood and adolescence range from 2% to 10% in nonreferred samples (APA 2013). Prevalence rates increase from infancy to adolescence and are higher in males than in females. Recent studies show prevalence rates of 9.5% (12% for males and 7.1% for females) (Nock et al. 2006). It seems that male-female ratios might be stronger in childhood than in adolescent-onset groups.

Although individuals with ASD often exhibit behavior problems that could have a negative impact in everyday activities, and several studies suggest a high prevalence of aggressive behavior in people with ASD, few studies have examined the prevalence of maladaptive behaviors that warrant a clinical diagnosis of CD in individuals with ASD. Prevalence of problem behaviors within the ASD population is relatively high. Most studies indicate that at least half of the people with ASD exhibit behavior problems, with an estimated prevalence ranging between 35.8% and 94.3% (Kozlowski and Matson 2012).

Lecavalier (2006) presented a study on prevalence of problem behaviors of children and adolescents with ASD. In a sample of 303 children and adolescents with ASD, he found that the proportion of children and adolescents who, according to parents and teachers, showed “conduct problems” was 13.9% (parents) and 8.4% (teachers). Behavior problems rated by parents and teachers as more frequent were stubbornness, temper tantrums, defiant behavior, arguing nature, not to accept being guilty, and explosive behavior. Stubborn behavior was rated as a moderate or severe problem for 50.7% (parents) and 44.4% (teachers). Also, temper tantrums, defiant behavior, not to accept being guilty, and explosive behavior were classified with a high frequency. Finally, aggressive acts, such as attacking others, were observed by teachers in 14.3% and in 9.9% by parents. Both informants (parents and teachers) indicate physical fights as moderate-to-serious problem for 5.3% of the sample. Property

destruction was a moderate or severe problem for 11–12% (according to information from parents and teachers, respectively), and threatening people was rated as a moderate-to-severe problem for 4.5% (parents) and 7.6% (teachers) of the sample. The study also found that lower adaptive skills were associated with greater problem behaviors among the sample.

Regarding high-functioning individuals with ASD, research and clinical observations suggest that a relatively large number of these individuals have behavioral problems at some point in their development. These symptoms may indicate the presence of ODD comorbid with ASD. They may also have symptoms of CD that are more severe in school-age time than in preschool (Gadow et al. 2005).

Natural History, Prognostic Factors, and Outcomes

The onset of CD can occur very early, even at preschool age, although the most obvious symptoms usually occur between middle childhood and middle adolescence. Onset is rare after age 16. ODD is a common precursor to the childhood-onset type. Other different factors affect the onset of symptoms of CD. The scientific literature highlights three main factors:

1. Personal characteristics such as a difficult temperament in early childhood, a callous-unemotional personality style (lack of empathy, remorselessness, and shallow affected), propensity for risk-taking, low to threatening and emotional reactions stimuli, reduced sensitivity to cues of punishment, and low levels of conscience and moral development
2. Bad parenting practices such as harsh, punitive, abusive, and/or inconsistent discipline
3. Repeated peer rejection and socializing with a deviant peer group (Hughes et al. 2008).

In addition, there is evidence suggesting that childhood-onset CD could be more related to personal and familial factors, whereas adolescent-onset could be more related to exposure to deviant

peers and environmental disadvantages associated with ethnic minority status (McCabe et al. 2001). Finally, CD in childhood is associated with other problems, including the likelihood of repeating a grade in school, being suspended or expelled from school, an earlier age of onset of alcohol dependence, and having to attend a greater number of treatments for drug abuse (Hughes et al. 2008). There is not a single risk factor that determines the onset of the CD. Experts emphasize that the multiple risk factors mentioned above interact to facilitate and perpetuate the disorder.

Problem behaviors play a critical role in ASD. However, the heterogeneity of symptoms present in persons with ASD (differences in cognitive functioning, or in adaptive behavior, the nature and severity of autistic behaviors) and changes in the development difficult to understand how these individual differences affect the occurrence and presentation of behavior problems beyond the core symptoms that define the ASD population.

Despite the differences, consequences of problem behaviors are similar in most cases. These behaviors prevent the development of social relationships (Matson et al. 2010; Myrbakk and von Tetzchner 2008), place the individual and their family members in very difficult situations, and interfere with effective education (Carr et al. 1991). Also, it has been shown that the fact of problem behaviors (specially aggressiveness) causing more distress to caregivers than the core autistic symptoms (Lecavalier et al. 2006) is one of the most important impediments to placement in less-restrictive environments (Shoham-Vardi et al. 1996), can also interfere with intervention efforts, and, if present during early childhood, is of particular concern given that these are critical years for intervention. Thereby problem behaviors impact the long-term prognosis.

Research on risk factors has provided some important data. Tonge and Einfeld (2003) studied a group of 118 children with autism in a period of 8 years. Results indicated that 73.5% of children with autism had behavioral alterations in a clinically significant range, with scores fairly stable over time. These researchers reported that children and adolescents with ASD are at high risk of severe and persistent behavioral disturbances

beyond those that define the disorder. Matson et al. (2009) have studied the potential causal factors of problem behaviors in children with ASD, showing that overall levels of problem behavior were positively correlated with severity of ASD (Matson et al. 2009). Lecavalier (2006) in his epidemiological study found that lower adaptive skills were associated with greater behavioral problems, but age and gender do not seem to influence behavior problems. In a recent study, Hartley et al. (2008) examined a large sample of children with ASD, classifying 27% of sample in the clinically significant range on the CBCL Externalizing Problems' subscale, and 22% fell within the clinically significant range on the aggression subscale. Results indicated that externalizing problems were significantly correlated with poorer adaptive skills, lower nonverbal cognitive functioning, and poorer expressive language. Also Dominick et al. (2007) found that individuals with ASD with low cognitive functioning and adaptive behavior and with low-expressive language skills exhibit more problem behavior than high-functioning individuals (Dominick et al. 2007).

Clinical Expression and Pathophysiology

CD may manifest itself in various symptoms that are classified into four categories: aggression toward people or animals, destruction of property without aggression, deception or theft, and serious violation of the social rules. These symptoms are behaviors that usually occur in early childhood. Many children commit acts of aggression, break property of others, commit petty thefts, say some lies, and violate some social rules. But in the case of children who have a CD, all these behaviors are very frequent and persistent, and some appear in an age too early such as running away from home at night (with no objective reasons to escape such as being abused) or truancy before age 13.

The clinical expression of problem behaviors in ASD will depend on the subject' age and on whether it is associated with ID individuals with greatest deficits engaging in more severe problem behaviors. Severity of ASD symptomatology

affects the severity of problem behaviors. Also, symptoms of other disorders such as attention-deficit hyperactivity disorder or obsessive compulsive disorder will affect the clinical expression of conduct problems in people with ASD. But it remains unknown whether the comorbidity of ASD with these disorders leads to different clinical expressions of behavior problems. This is important to better understand the pathophysiology of CD (and also of ASD). The neurobiological disorder of ASD results in difficulties in social cognition with its own characteristics, such as the difficulty to infer mental states and recognize (e.g., intentions, beliefs, desires, etc.) in self and others, which can interact with environmental factors leading to atypical behavioral patterns and behavior problems.

Some CD symptoms (such as physical aggression, lying, and stealing) are relatively common in early childhood, and to distinguish them from normal childhood behavior, the clinician must take into account the frequency and persistence of problem behavior beyond the age of four. In childhood, most of the manifestations are limited to family and school contexts, but they affect the overall functioning of the child. In adolescence, behavior problems tend to have more serious consequences encompassing the whole adolescent's social setting and including behavior problems that are much more serious.

Evaluation and Differential Diagnosis

CD is a complex problem affecting multiple domains of functioning and often showing a high rate of comorbidity with other disorders. Assessment requires a comprehensive approach encompassing the child, family, school, peers, and community factors. Well-trained professionals should conduct assessments, to ensure the proper treatment. Otherwise, the behavior problems will continue or even worsen.

Language disorders and intellectual disability usually found in ASD complicate the assessment and diagnosis. Even mild deficiencies in language can make challenging the study and identification of subtle differences in emotions, health status

(presence of pain or physical discomfort), or feelings of annoyance at being unable to control own decisions.

Assessment requires combining qualitative and quantitative methods to obtain information, and collecting data from several sources such as parents, teachers, and peers is mandatory. Information from different sources should be compared to detect and prevent possible biases caused by the partial view of each reporter and for a better understanding of the disorder being evaluated.

Behavior rating scales can be completed by parents, teachers, and children to obtain comparable information. Clinicians and researchers consider behavior rating scales a time-efficient method of collecting reliable information and providing an assessment of several domains of behavior, usually both on the healthy functioning and the maladaptive.

Behavioral observation is a useful tool that is normally used in assessing problem behaviors, both to describe the function (i.e., functional assessment) of problem behavior and to monitor treatment progress. Functional assessment is the process of identifying the variables that predict and maintain problem behavior. The literature review on the treatment of problem behaviors suggests that interventions based on functional assessment are more likely to produce the reduction of problem behavior (Homer et al. 2002). The process of conducting a functional assessment typically involves the following: (1) identifying the problem behavior, (2) building hypotheses about the events that occasion and maintain problem behavior, (3) testing/confirming the functional hypothesis, and (4) designing an intervention based on the confirmed information (Homer et al. 2002).

Treatment

A variety of treatment procedures have been developed for children and adolescents with CD, but only some have been shown to reduce CD behaviors. Intervention procedures seem to be more effective in children under 8 years, when behavior problems have recently begun and when it includes a multimodal and multicomponent

strategy, specifically adapted to the individual needs (Hughes et al. 2008).

The evidence-based recommendations emphasize the need for a multicomponent intervention aimed at prevention and early intervention. The treatment mainly consists of psychological, educational, and social interventions focusing on children, parents, and teachers. Psychotropic medication and applied behavior analysis are the most frequently used treatments.

Child-directed interventions aim to improve skills to manage anger and control of aggressive impulses, and improve empathy with others, strengthening relationships with peers. With the family it is necessary first to ensure commitment and motivation and then to begin training within the family context and subsequently generalized to other places of the community (INSERM 2005). Pharmacological treatment is appropriate when used in the context of a comprehensive psychoeducational evaluation and provided as part of a global treatment strategy (Connor 2002).

The best practice for psychoeducational treatment of behavior problems should be based on principles and methods of positive behavior support (Rogers and Vismara 2008). That is, it should be a treatment that uses functional assessment to determine the function (or functions) of problem behavior. After identifying the function, a positive behavior support plan must be designed and implemented, aimed at teaching new functional behaviors that serve to replace the problem behavior. Horner et al. (2002) suggest that a support plan should take into account several elements, and a few of those are as follows:

1. Prevent behavior problems by organizing the environment in order to experience less negative events and greater accessibility of rewarding activities.
2. If there are behavioral problems, conduct a functional assessment.
3. Build a behavioral intervention to make the problem behavior irrelevant, by teaching socially appropriate behaviors that make the person much more competent in the context and produce the same effect in the context of the problem behavior.
4. Organize the consequences for appropriate behavior to compete with problem behavior, avoiding also the reinforcement of problem behavior.
5. Ensure that the procedures are within the skills, resources, and values of those who must implement them.

Parent training based on principles of applied behavior analysis has great empirical support. Successful programs for individuals with ASD and problem behavior include a parent training component usually based on principles of applied behavior analysis. Common parent training elements include teaching behavioral principles and management techniques, role-playing, homework assignments, teaching play and social skills, use of visual schedules, and home visits or telephone consultation, among others.

Pharmacotherapy is common among individuals with ASD with behavior difficulties. The most used agents include selective serotonin reuptake inhibitors, antipsychotics, alpha 2 adrenergic agonists, psychostimulants, and anticonvulsants. But empirical support for use of these agents in ASD varies widely. A classic study on the use of Risperidone (McCracken et al. 2002) concluded that this psychoactive drug is effective and well tolerated for the treatment of tantrums, aggression, or self-injurious behavior in children with ASD, although the short period of the trial in this study limits inferences about adverse effects. Risperidone, like other atypical antipsychotics, is associated with adverse events, such as weight gain, and the subsequent risk of metabolic syndrome. A recent trial by Aman et al. (2009) tested whether combined treatment with risperidone and parent training in behavior management is superior to medication alone in improving severe behavioral problems. Results indicated that parent training plus medication produced greater reduction of problem behavior than medication alone in children with ASD.

Confidentiality

Celia Tam¹ and James C. McPartland²

¹Yale Child Study Center, New Haven, CT, USA

²School of Medicine, Child Study Center, Yale University, New Haven, CT, USA

Definition

Confidentiality refers to a general standard of professional conduct, as well as, in some cases, the legal requirement for providers and/or

researchers to maintain the privacy of a patient's personal health information and records unless consent to release the information is obtained from the patient. In the case of minors, this consent may be obtained from the patient's parent(s) or legal guardian(s), and rules around confidentiality related to minors may vary by state.

Historical Background

Confidentiality is important in order to establish trust between providers and patients and to protect patient privacy. Confidentiality can be bound by both ethical and legal standards. For example, the American Psychological Association's Ethical Principles of Psychologists and Code of Conduct provides ethical guidelines regarding a psychologist's obligation to take reasonable precautions to protect confidential information related to the patient (Standard 4; APA 1992). In 1996, The U.S. Department of Health and Human Services (HHS) established the Health Insurance Portability and Accountability Act (HIPAA), Public Law 104–191, and issued a Privacy Rule to implement the legal requirement for providers to protect the privacy of a patient's medical records or personal health information, including information related to mental health. In the case of minors, according to HIPAA, parents have the legal right to access their child's records and personal information. In certain specific situations, providers may share information without the patient's consent. Common exceptions may include cases that involve a court order to release protected information, cases in which there is suspicion of domestic violence, abuse or neglect of children, the elderly, or people with disabilities, or in order to protect the patient or the public from serious harm (Tarasoff 1974, 1976).

Current Knowledge

Since it was created, the HIPAA has undergone several revisions and updates in order to further protect the confidentiality and privacy of health information, including electronic protected health

information (PHI). In 2002, the HHS modified the Privacy Rule associated with HIPAA to set national standards for the protection of individually identifiable health information by health plans, health care clearinghouses, and health care providers. In 2003, HHS published a final Security Rule to set national standards for protecting the confidentiality of electronic PHI.

Future Directions

Confidentiality remains a sensitive and, at times, controversial topic, particularly as it relates to determining exceptions or limitations to confidentiality, such as in the treatment of minors or when the risks may outweigh the benefits (e.g., Tarasoff 1974, 1976). Some have proposed guidelines and recommendations related to dealing with issues of confidentiality when working with various populations (APA 1992; Gustafson and McNamara 1987; Koocher and Keith-Spiegel 1990). Future investigations may focus on further delineating the ethical and legal boundaries and limits around cases of confidentiality. Furthermore, research should explore the important considerations to make with regards to assessing competence and respecting confidentiality in individuals with autism spectrum disorders and other developmental disabilities.

Congenital Disorders

Claudia Califano

Yale-New Haven Hospital, New Haven, CT, USA

Definition

Congenital disorders are those disorders that are present at the time of birth and involve an abnormality of structure and/or function that has arisen during development. Congenital disorders are not necessarily genetic though do include genetic disorders. All genetic disorders are congenital as they are present at birth even if they are not yet detected at birth. Congenital disorders may arise as a result of the intrauterine environment, errors in embryonic development, and infections. The outcome of such disorders varies widely and is dependent upon the disorder itself and the availability of possible postnatal treatments. Examples of congenital disorders include diseases such as cystic fibrosis, physical anomalies such as having a sixth finger on the hand, metabolic diseases such as congenital adrenal hyperplasia, and trisomy 21 which is also known as Down syndrome.

Conners' Continuous Performance Test

Renee Folsom¹ and Philip Levin²

¹Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles (UCLA) The Help Group/UCLA Neuropsychology Program, Los Angeles, CA, USA

²The Help Group – UCLA Neuropsychology Program, Los Angeles, CA, USA

Synonyms

CCPT; CPT; CPT-II

Description

The Conners' Continuous Performance Test is an attention test for research and clinical settings (Conners 1995). It is used for measuring processes related to vigilance, response inhibition, signal detection, and other aspects of performance

(Conners et al. 2003). The test is presented in a game-like format where 360 letters (approximately 1 in. in size and bold faced) appear on the computer screen, one at a time, for approximately 250 ms. Respondents are required to press the space bar or click the mouse button when any letter *except* the letter "X" appears on the screen (Conners and MHS Staff 2000). The CPT-II standard paradigm consists of six blocks, with each block divided into three 20-trial sub-blocks. Each sub-block has a separate inter-stimulus interval (i.e., the time in between the letter presentations). The inter-stimulus intervals (ISIs) are 1, 2, or 4 s. The order of the three different ISI conditions varies from block to block (Conners et al. 2003). The CPTII can be completed in 14 min. The test can be administered to participants 6 years of age and above.

After the test session, the program generates a report that includes response times, omission errors (i.e., when a response is not given after a non-X appears on screen), commission errors (i.e., when a response is given after an X appears on screen), change in reaction time speed and consistency as the test progresses, and change in reaction time speed and consistency for different inter-stimulus intervals. Examination of the results by blocks and varying ISIs allows for the assessment of vigilance and the ability to adjust to changing tempo and task demands (Conners and MHS Staff 2000).

Historical Background

The continuous performance test was first introduced by Rosvold and colleagues in 1956 (Spreen and Strauss 1998) to detect lapses of attention in patients with petit mal epilepsy. In this early version, the participants were required to press a key in response to a rare target, such as the letter "X." Subsequent CPTs have made changes to this original paradigm including having the participants press a key when the target letter is preceded by another letter (e.g., "X" preceded by "A") or upon the second successive presentation of a letter (e.g., S-S). There have also been variations with regard to modality (i.e., visual or auditory), the type of

stimuli (e.g., letters, numbers, colors, or geometric figures), and the type of data that are evaluated (e.g., omissions, commissions, inter-stimulus interval, measures of sensitivity; Spreen and Strauss 1998).

Conners' introduction of his version of the CPT in 1995 represented a departure from the more traditional CPT paradigm. In the earlier versions, participants typically sit passively while observing the presentation of nontarget stimuli and must respond to the occasional target stimulus (usually an "X"). In Conners' version, which is also sometimes called the "not-X" CPT, participants are asked to press a button on each trial (usually letters), except for the letter X. Barkley (2006) notes that this task requires a different form of response inhibition. Conners et al. explain that Conners' "not-X" CPT places a greater demand on response inhibition due to the frequent responding interrupted by the occasional nontargets (the less probable "X") as opposed to the more passive responding of the conventional "X" task.

Conners has since come out with an updated version of his CPT, the Conners' Continuous Performance Test (2nd ed.; Conners' CPT-II; Conners and MHS Staff 2000). The updated version differs from the previous version in that it is based on new and expanded norms that include a large subsample of neurologically impaired individuals. This allows for comparison of responses to general population norms, ADHD norms, and neurologically impaired norms. The program itself includes validity checks to flag certain conditions that may adversely affect CPT II administration and a Confidence Index that enables the practitioner to gauge the certainty of the assessment/classification.

Psychometric Data

The CPT-II normative data included 2,521 participants. Of this, 1,920 were healthy individuals from the general population, 378 were diagnosed with Attention-Deficit/Hyperactivity Disorder (ADHD), and 223 were adult individuals identified with some type of neurological impairment

(e.g., head injuries, dementias). Normative data were collected from 30 sites in 16 states and three Canadian provinces. The multi-site, nonclinical data came from schools, organizations, science centers, and controlled research settings. The norms were divided into eight age groups. For children of ages 4 through 17, norms were provided in 2-year increments. For adults aged 18 and older, they were divided into three age groups (18–34, 35–54, and 55 +). The applicability of CPT-II norms to Asian and African American groups was also assessed. Scores for the Asian group were consistent with those obtained in the general population. However, the African American group made slightly fewer commission errors than the general population, and showed slightly better discriminatory power as measured by the statistic d' prime. Overall, the general population norms were reportedly applicable to these minority groups. In fact, there were no significant differences on the overall profile indexes (Conners and MHS Staff 2000).

Three types of reliability information were provided on the CPT-II manual: Split-half reliability, test-retest reliability, and standard error of measurement (Conners and MHS Staff 2000). The split-half reliability information from the original CPT was cited. These appeared adequate and ranged from 0.66 to 0.95. Test-retest reliability was obtained using 23 participants in the standardization of the CPT-II. The average interval between administrations was 3 months. The test-retest reliability estimates ranged from 0.05 to 0.92 with most of the variables showing good consistency across administrations. However, the Block change and ISI change statistics have low test-retest correlations, suggesting that these variables do not produce good consistency across administrations. When measures are combined into indices for ADHD and neurological assessment, the test-retest reliabilities were excellent, 0.89 and 0.92 respectively. Using the same test-retest data, it was also demonstrated that the CPT-II had no significant practice effect. In addition, information on standard error of measurement and standard error of prediction for the various CPT-II measures across gender and age was presented.

Conners and the MHS Staff (2000) cited research to support the clinical utility of the CPT. In a study based on the original standardization sample, significant differences were seen between the ADHD group and other diagnoses across most of the CPT variables. The ADHD group responded more slowly, had greater variability of reaction times, made more omission and commission errors, and was more affected by changes in ISI. In similar analyses using the updated CPT-II data, no significant difference was observed between ADHD and nonclinical groups; for all other analyses, there was a large and significant difference between ADHD and nonclinical groups with the ADHD groups performing worse on all of the measures. For the adults aged 18 years and older, planned comparisons were done to see if the nonclinical group differed from the clinical groups, and if the two clinical groups differed from each other. As predicted, the clinical groups performed significantly worse than the nonclinical group. Compared to the ADHD group, the Neurological group made significantly more omission errors, had significantly slower reaction times, and was significantly less consistent across the interstimulus intervals.

Clinical Uses

The CPT paradigm has traditionally been included in evaluations for ADHD. Barkley (2006) states that, "A wide-ranging literature has shown it to be the most reliable of psychological tests for discriminating groups of children with ADHD from nondisabled children" (p. 377). Spren, Risser, and Edgell (1995) report that on a continuous performance task hyperactive children make more errors of omission and of commission, show more rapid deterioration in performance than controls, and are less able to inhibit premature or repetitive responding, indicating poor impulse control. Lezak, Howieson, and Loring (2004) state that on the CPT, adults with ADHD have a high reaction time variability and higher rate of commission errors than control subjects, which suggests that they have trouble inhibiting responses. According to Spren

and Strauss, the CPTs have also been shown to distinguish between normal controls and certain patient groups including adults with head injuries and children with conduct disorder, learning disabilities, and those at high risk for schizophrenia. In addition, Barkley and Spren and Strauss report that CPTs are sensitive to stimulant drug effects among children and adolescents with ADHD.

Barkley has raised some concern about the diagnostic utility of the Conners' CPT, in particular, in ADHD assessments. Citing one study that investigated associations between Conners' CPT scores and several other measures, including parent and teacher ratings as well as neuropsychological and achievement tests, Barkley reported that the Conners CPT's overall index failed to relate to parent and teacher ratings. In addition, only half of those participants who met criteria for ADHD "failed" the CPT. Barkley also reported poor discriminant validity, in that children with a reading disability actually performed more poorly than children with ADHD. In another study on the ecological validity of the CPT-II in a school-based sample, Barkley cited findings showing nonsignificant relationships between CPT performance and three other kinds of measures (parent ratings, teacher ratings, and classroom observations). He also reported negative correlation between IQ and omission errors on the CPT-II, suggesting that the CPT-II may measure letter recognition skills or phonological awareness rather than impulsivity or inattention per se.

Despite these concerns, Barkley still holds that the CPT is the only psychological measure that seems to directly assess the core symptoms of ADHD, namely, impulsivity and attention. However, he warns that if a child performs well on this measure, it does not indicate that the child is nondisabled or without ADHD because of the high rate of false negatives (i.e., children who are rated by parents and teachers as having ADHD, but who obtain average scores on the test) associated with CPTs. He joins Conners (2000) in reminding the clinician that the test provides one source of information to be integrated with other sources (e.g., self-report data, observer-based data, historical information, interview data,

and results from other tests) in reaching a final diagnostic decision.

The use of continuous performance tests in assessing children with autism spectrum disorders is less common. Three studies were found but none of them used the Conners' CPT-II. In the first study, 23 children with autism were compared with two control groups (one matched based on verbal mental age and another based on performance mental age) on several attention measures including three versions of the traditional CPT paradigm (Pascualvaca et al. 1998). The results showed that none of the CPT versions differentiated between the groups. In the second study, Schatz, Weimer, and Trauner (2002) explored the use of the Test of Variables of Attention (TOVA) in assessing attention deficit symptoms in a group of eight children and young adults with Asperger's Syndrome (AS). The TOVA is a continuous performance test that is similar to the Conners' CPT but with an additional auditory component. Five of eight subjects with AS received scores that suggested the presence of an attention deficit, whereas only two of eight subjects received scores suggestive of an attention deficit. The authors looked at this as a pattern that could be explored using a bigger sample. In the third study, Corbett and Constantine (2006) compared children with autism spectrum disorder (ASD) with those that have been diagnosed with ADHD and typically developing children using the Integrated Visual and Auditory Continuous Performance Test, another version of a CPT. They found that children with ASD show significant deficits in visual and auditory attention and greater deficits in impulsivity than children with ADHD or typically developing children. The authors note that the findings suggest that many of the children with ASD demonstrate significant ADHD-like symptoms. They point out that this study adds to the growing literature that calls into question the current exclusionary practice of offering a diagnosis of ADHD in pervasive developmental disorders.

Two other variables that might be relevant in the performance of individuals with autism spectrum disorders on the CPT-II are anxiety and intelligence. Conners and the MHS Staff presented data showing that anxiety may affect a participant's CPT-II response style and lead to

response inhibition for physiological anxiety, and decrease in response inhibition for cognitive anxiety. In terms of intelligence, the manual included two studies that showed nonsignificant correlations between IQ as measured by the WISC and CPT performance. Still it was noted in the manual that some individuals with severe cognitive impairment, agitation, or severe psychotic symptoms cannot be administered the CPT-II.

Conners' Parent Rating Scale

Hillary Hurst

Department of Psychology, University of
Massachusetts Boston, Boston, MA, USA

Description

The Conners' Parent Rating Scale (CPRS) is a parent-report measure that assesses children's problem behaviors, particularly symptoms of attention deficit hyperactivity disorder (ADHD) and related disorders (including oppositional defiant disorder and conduct disorder). At the time of publication, the Conners 3-P (2008) is the current version of the CPRS. Parents of children with autism spectrum disorders may be asked to complete the Conners 3-P because of the shared symptoms between ADHD and autism spectrum disorders. The Conners 3-P was developed by C. Keith Conners, Ph.D., who also designed two related measures: the Conners' Teacher Rating Scales (CTRS), a teacher-report measure, and the Conners' Self-Report Scales (CSRS), a self-report measure for children and adolescents. Because these measures are meant to be used in conjunction, the family of Conners' tests is considered to be a "multi-informant" mode of assessment. This is valuable because it can yield information about children's behaviors in multiple settings. For example, asking a parent to complete the Conners 3-P and asking a teacher to complete the Conners 3-T (for "teacher") can shed light on how a child's behavior may differ between home and school.

Historical Background

Gianarris, Golden and Greene (2001) provide a detailed overview of the multiple versions of the Conners' Parent Rating Scales. The roots of the Conners 3-P date back to the 1960s, when C. Keith Conners, Ph.D., created behavior rating scales based on his multiple observations of children and adolescents with behaviors consistent

with what is now known as ADHD. He performed factor analysis to determine how these behaviors fit together and first published his findings in 1970. One of the earliest aims of Conners' work was to track changes in children's behavior following medication use. In 1973, Conners released a 93-item checklist of behaviors that came to be known as the original Conners' Parent Rating Scale. It was quickly adopted as a diagnostic tool even though it did not have a normative sample of the kind structured for empirical support that is required to establish a new assessment tool today. It was not until 1989 that Conners' sample was formalized and expanded, and that the CPRS was published and shared widely. In 1998, the CPRS-R (for "revised") was released, and in 2008, the third and most recent edition, the Conners 3-P, was released. The Conners 3-P is currently available in English and Spanish. The similarities and differences between these versions are explored below in the section "[Psychometric Data](#)."

Psychometric Data

The format and response style of the measure have remained quite consistent throughout the revisions of the Conners 3-P. In all three versions, the respondent (the parent completing the measure) is asked to reflect on his or her child's actions over the past month and to respond to a series of items describing mainly problem behaviors (e.g., "gets distracted when given instructions to do something"). For each item, the respondent is asked to mark 0 ("not true at all/never/seldom"), 1 ("just a little true/occasionally"), 2 ("pretty much true/often/quite a bit"), or 3 ("very much true/very often/very frequent") to describe the extent to which their child engages in or demonstrates the given behavior.

The Conners 3-P has a long-form version (110 questions), a short-form version (45 of the 110 total questions), an ADHD Index (10 of the 110 total questions), and a Global Index (10 of the 110 questions). Previous versions also offered longer and shorter forms. There are circumstances in which one form would be preferable over

another; this largely has to do with the reason for testing. For example, using the long-form version of the Conners 3-P might be preferable to using one of the shorter forms when conducting an initial assessment.

Revisions were made (e.g., transitioning from the CPRS to the CPRS-R, and again from the CPRS-R to the Conners 3-P) in order to strengthen the psychometric properties of the instrument. Most available literature focuses on the psychometric properties of the CPRS-R and the Conners 3-P. The CPRS-R contains the following subscales: Oppositional (long and short forms), Social Problems (long form only), Cognitive Problems/Inattention (long and short forms), Psychosomatic (long form only), Hyperactivity (long and short forms), DSM-IV Symptom Subscales (long form only), Anxious-Shy (long form only), ADHD Index (long and short forms), Perfectionism (long form only), and Conners' Global Index (long form only). The same subscales appear on the CTRS-R with the exception of the Psychosomatic subscale, which is not included. Both raw scores and T scores are generally reported for each subscale; T scores are standardized scores with a mean of 50 and a standard deviation of 10. For example, a child with a T score of 50 on the Oppositional subscale would have about the same level of oppositional behaviors as the average child his or her age in the normative sample. Higher T scores are associated with higher levels of problem behaviors.

Internal consistency coefficients of the CPRS-R (in other words, measures of how well the individual items of the measure "hang" together and form the subscales listed above) for the total sample range from .77 to .96. The test-retest reliability coefficients – a measure of how similarly a child will be rated shortly following an initial assessment with the CPRS-R – range from .47 to .86. As previously discussed, the CPRS-R is designed to be sensitive to changes in behavior, particularly following medication use, and this might explain partially the lower test-retest reliability coefficients.

Some significant changes were made to the CPRS-R to create the Conners 3-P. The publishers of the Conners 3-P point to the large normative sample ($n = 1200$) that reflects the 2000 US

Census information on race and ethnicity, gender, and parental education level as particular strength of the measure. While the test creators were careful to include a diverse normative sample in their development of the Conners 3-P, it is important to point out that the validity of the Conners' tests in diverse cultures has not yet been established and represents an active area to study. The Conners 3-P includes the use of 1-year, instead of 3-year, age bands to compare children's scores to the normative sample (e.g., 4-year-olds are now compared only to other 4-year-olds, instead of to 4-, 5-, and 6-year-olds). Also, the Conners 3-P includes optional combined gender norms for boys and girls – the norms had been strictly separated by gender in the previous versions – and the combined norms can be helpful for understanding behavior within the context of settings, such as the classroom, that are very frequently coed. The Conners 3-P also has a greater focus on differential diagnosis (or, in other words, teasing apart symptoms of ADHD from symptoms of related disorders) and this is reflected in its normative sample. Additionally, the age range of the Conners 3-P, at 6–18 years old, is slightly narrower than the age range, 3–17 years, of the previous CPRS versions. The age range was extended to 18 years, 11 months to capture adjustment through the end of high school; it was limited to 6 years, 0 months so that early experiences can be assessed more thoroughly with a separate measure, the Conners Early Childhood (EC).

The Conners 3-P contains the following content scales: inattention, hyperactivity/impulsivity, learning problems, executive functioning, aggression, and peer/family relations. It also contains four symptoms scales – ADHD Inattentive, ADHD Hyperactive-Impulsive, Conduct Disorder, and Oppositional Defiant Disorder – that map onto the diagnostic criteria put forth in the Diagnostic and Statistical Manual of Mental Disorders, fourth edition, text revision (DSM-IV-TR). New to the Conners 3-P include validity scales (which indicate how a parent is responding to the items and whether or not the information he or she provides is interpretable), screening items for childhood anxiety and depression, critical items (which require immediate follow-up by the researcher or clinician administering the

measure), and impairment items (which indicate decreased functioning in certain life areas, like social relationships). The Conners 3-P is also notable for the way in which it maps onto the Individuals with Disabilities Education Act (IDEA); in other words, how a child is rated by his or her parent on the Conners 3-P might carry implications for the services he or she is eligible to receive in school.

Both test-retest reliability and internal consistency have been found to be very good for the Conners 3-P, and for the overall family of Conners 3 assessments. According to data put forth by the publisher, internal consistency coefficients (in other words, measures of how well the individual items of the measure “hang” together and form the subscales listed above) for the overall content scales is .91 and for the DSM-IV-TR scales, .90. A breakdown of internal consistency coefficients by Conners 3-P subscale are the following: inattention = .93, hyperactivity/impulsivity = .94, learning problems = .90, executive functioning = .92, aggression = .91, peer relations = .85, ADHD Inattentive = .93, ADHD Hyperactive-Impulsive = .92, Conduct Disorder = .83, and Oppositional Defiant Disorder = .83. The 2–4-week test-retest reliability coefficients – a measure of how similarly a child will be rated 2 weeks and again 4 weeks following an initial assessment with the Conners 3-P – was also very good in the overall Conners’ sample (Cronbach’s alpha = .71 to .98, with all correlations significant at the $p < .001$ level). Inter-rater reliability coefficients (a measure of how likely two different respondents, such as a mother and father, or a parent and teacher, are to rate the same child’s behavior) in the overall Conners’ sample are also acceptable to excellent, ranging from .52 to .94. Continuity between the CPRS-R and the Conners 3-P was demonstrated, and tests of factorial, convergent, divergent, and discriminant validity were also performed on the Conners 3-P.

The Conners 3-P may indicate whether a child’s symptoms are consistent with ADHD or a related disorder. While it includes questions about different symptoms in parent-friendly and accessible language, it does not elicit all of the information that would be needed to make a formal diagnosis. It is important to note that a high score on the Conners 3-P alone is not sufficient to diagnose a child; instead, it is only one piece of information that clinicians will consider when making a diagnosis, if one is warranted. If a child has a diagnosis, then the Conners 3-P can be used to track changes in his or her behavior over time; this is especially important if a child receives intervention, medication, or special services to address his or her behavioral challenges. Sometimes, the Conners 3-P is used in the absence of any behavioral problems – it can be used as a screener, or in a routine manner.

Because of the overlap between behaviors – particularly externalizing ones – associated with ADHD and those associated with autism spectrum disorders, it is helpful to understand the function of the Conners 3-P. Also, since autism spectrum disorders sometimes coexist with intellectual disabilities (ID), it is important to understand how the psychometric properties of the Conners’ tests hold up among children with ID. Deb, Dhaliwal and Roy (2008) undertook this research with the CPRS-R and the CTRS-R and found that parents and teachers differed significantly in how they rated children with ID (whereas significant correlations between their reports would be expected, based on previously published psychometric data). Also, the authors noted that some of the items were not applicable to children with severe or profound ID, and/or who were nonverbal (as are some children with autism spectrum disorders). These findings have implications for using the Conners’ tests to assess children with known autism spectrum disorders and ID.

Clinical Uses

The Conners 3-P is a useful tool when a child is experiencing behavioral difficulty at home or at

Conners' Teacher Rating Scale

Hillary Hurst

Department of Psychology, University of Massachusetts Boston, Boston, MA, USA

Description

The Conners' Teacher Rating Scale (CTRS) is a teacher-report measure that assesses children's problem behaviors, particularly symptoms of attention deficit hyperactivity disorder (ADHD) and related disorders (including oppositional defiant disorder and conduct disorder). At the time of publication, the Conners 3-T (2008) is the current

version of the CTRS. Teachers of children with autism spectrum disorders or suspected autism spectrum disorders may be asked to complete the Conners 3-T because of the shared symptoms between ADHD and autism spectrum disorders. The Conners 3-T was developed by C. Keith Conners, Ph.D., who also designed two related measures: the Conners' Parent Rating Scales (CPRS), a parent-report measure, and the Conners' Self-Report Scales (CSRS), a self-report measure for children and adolescents. Because these measures are meant to be used in conjunction, the family of Conners' tests is considered to be a "multi-informant" mode of assessment. This is valuable because it can yield information about children's behaviors in multiple settings. For example, asking a teacher to complete the Conners 3-T and a parent to complete the Conners 3-P can shed light on how a child's behavior may differ between home and school.

Historical Background

The Conners 3-T shares a great deal of history with the Conners 3-P. The roots of these assessments date back to the 1960s, when C. Keith Conners, Ph.D., created behavior rating scales based on his multiple observations of children and adolescents with behaviors consistent with what is now known as ADHD. He performed factor analysis to determine how these behaviors fit together and first published his findings in 1970. One of the earliest aims of Conners' work was to track changes in children's behavior following medication use. In 1973, Conners released a 93-item checklist of behaviors that came to be known as the original Conners' Parent Rating Scale. It was quickly adopted as a diagnostic tool even though it did not have a normative sample of the kind structured for empirical support that is required to establish a new assessment tool today. It was not until 1989 that Conners' sample was formalized and expanded, and that the CTRS, along with the CPRS, was published and shared widely. In 1998, the CTRS-R (for "revised") was released, and in 2008, the third and most recent edition, the Conners 3-T, was

released. The Conners 3-T is currently available in English and Spanish. The similarities and differences between these versions is explored below in the section “[Psychometric Data](#).”

Psychometric Data

The format and response style of the measure have remained quite consistent throughout the revisions of the Conners 3-T. In all three versions, the respondent (the teacher completing the measure) is asked to reflect on his or her student's actions over the past month and to respond to a series of items describing mainly problem behaviors (for example, “leaves seat when he/she should stay seated”). For each item, the respondent is asked to mark 0 (“not true at all/never/seldom”), 1 (“just a little true/occasionally”), 2 (“pretty much true/often/quite a bit”), or 3 (“very much true/very often/very frequent”) to describe the extent to which their student engages in or demonstrates the given behavior.

The Conners 3-T has a long-form version (115 questions), a short-form version (41 of the 110 total questions), an ADHD Index (10 of the 110 total questions), and a Global Index (10 of the 110 questions). Previous versions also offered longer and shorter forms. There are circumstances in which one form would be preferable over another; this largely has to do with the reason for testing. For example, using the long-form version of the Conners 3-T might be preferable to using one of the shorter forms when conducting an initial assessment.

Revisions were made (e.g., transitioning from the CTRS to the CTRS-R, and again from the CTRS-R to the Conners 3-T) in order to strengthen the psychometric properties of the instrument. Most available literature focuses on the psychometric properties of the CTRS-R and the Conners 3-T. The CTRS-R, like the CPRS-R, contains the following subscales: Oppositional (long and short forms), Social Problems (long form only), Cognitive Problems/Inattention (long and short forms), Hyperactivity (long and short forms), DSM-IV Symptom Subscales (long form only), Anxious-Shy (long form only),

ADHD Index (long and short forms), Perfectionism (long form only), and Conners' Global Index (long form only). Unlike the CPRS-R, the CTRS-R does not contain the Psychosomatic subscale. Both raw scores and T scores are generally reported for each subscale; T scores are standardized scores with a mean of 50 and a standard deviation of 10. For example, a child with a T score of 50 on the Oppositional subscale would have about the same level of oppositional behaviors as the average child his or her age in the normative sample. Higher T scores are associated with higher levels of problem behaviors.

Internal consistency coefficients of the CPRS-R (in other words, measures of how well the individual items of the measure “hang” together and form the subscales listed above) for the total sample range from .77 to .96. The test-retest reliability coefficients – a measure of how similarly a child will be rated shortly following an initial assessment with the CPRS-R – range from .47 to .86. As previously discussed, the CPRS-R is designed to be sensitive to changes in behavior, particularly following medication use, and this might explain partially the lower test-retest reliability coefficients.

Some significant changes were made to the CTRS-R to create the Conners 3-T. The publishers of the Conners 3-T point to the large normative sample ($n = 1200$) that reflects the 2000 US Census information on race and ethnicity, gender, and parental education level as particular strength of the measure. The Conners 3-T includes the use of 1-year, instead of 3-year, age bands to compare children's scores to the normative sample (e.g., 4-year-olds are now compared only to other 4-year-olds, instead of to 4-, 5-, and 6-year-olds). Also, the Conners 3-T includes optional combined gender norms for boys and girls – the norms had been strictly separated by gender in the previous versions – and the combined norms can be helpful for understanding behavior within the context of settings, such as the classroom, that are very frequently coed. The Conners 3-T also has a greater focus on differential diagnosis (or, in other words, teasing apart symptoms of ADHD from symptoms of related disorders) and this is reflected in its normative sample. Additionally,

the age range of the Conners 3-T, at 6–18 years old, is slightly narrower than the age range, 3–17 years, of the previous CTRS versions. The age range was extended to 18 years, 11 months to capture adjustment through the end of high school; it was limited to 6 years, 0 months so that early experiences can be assessed more thoroughly with a separate measure, the Conners Early Childhood (EC).

The Conners 3-P contains the following content scales: inattention, hyperactivity/impulsivity, learning problems, executive functioning, aggression, and peer relations. It also contains four symptoms scales – ADHD Inattentive, ADHD Hyperactive-Impulsive, Conduct Disorder, and Oppositional Defiant Disorder – that map onto the diagnostic criteria put forth in the Diagnostic and Statistical Manual of Mental Disorders, fourth edition, text revision (DSM-IV-TR). New to the Conners 3-T include validity scales (which indicate how a teacher is responding to the items and whether or not the information he or she provides is interpretable), screening items for childhood anxiety and depression, critical items (which require immediate follow-up by the researcher or clinician administering the measure), and impairment items (which indicate decreased functioning in certain life areas, like social relationships). The Conners 3-T is also notable for the way in which it maps onto the Individuals with Disabilities Education Act (IDEA); in other words, how a child is rated by his or her teacher on the Conners 3-T might carry implications for the services he or she is eligible to receive in school.

Both test-retest reliability and internal consistency have been found to be very good for the Conners 3-T, and for the overall family of Conners 3 assessments. According to data put forth by the publisher, internal consistency coefficients (in other words, measures of how well the individual items of the measure “hang” together and form the subscales listed above) for the total sample range from .77 to .97. The 2–4-week test-retest reliability coefficients – a measure of how similarly a child will be rated 2 weeks and again 4 weeks following an initial assessment with the Conners 3-T – was also very good (Cronbach's $\alpha = .71$ to .98, with all correlations significant

at the $p < .001$ level). Inter-rater reliability coefficients (a measure of how likely two different respondents, such as a mother and father, or a parent and teacher, are to rate the same child's behavior) are also acceptable to excellent, ranging from .52 to .94. Continuity between the CTRS-R and the Conners 3-T was demonstrated, and tests of factorial, convergent, divergent, and discriminant validity were also performed on the Conners 3-T.

Clinical Uses

The Conners 3-T is a useful tool when a child is experiencing behavioral difficulty at school or at home. The Conners 3-P may indicate whether a child's symptoms are consistent with ADHD or a related disorder. While it includes questions about different symptoms in user-friendly and accessible language, it does not elicit all of the information that would be needed to make a formal diagnosis. It is important to note that a high score on the Conners 3-T alone is not sufficient to diagnose a child; instead, it is only one piece of information that clinicians will consider when making a diagnosis, if one is warranted. If a child has a diagnosis, then the Conners 3-T can be used to track changes in his or her behavior over time; this is especially important if a child receives intervention, medication, educational supports, or other services to address his or her behavioral challenges. Sometimes, the Conners 3-T is used in the absence of any behavioral problems – it can be used as a screener, or in a routine manner.

Frick, Barry, and Kamphaus (2009) note that the Conners 3-T has several strengths that suit it well for school-based assessments. For example, it focuses on ADHD and other disorders involving externalizing behaviors that can interfere with children's school performance. Also, its short versions, with demonstrated validity and reliability, may be more accessible and user-friendly for teachers in busy school environments. However, the Conners 3-T has its drawbacks too, which include minimal assessment of childhood depression and anxiety, which frequently include

internalizing symptoms. Also, the normative sample of the Conners 3-T is racially and ethnically diverse, but not to the same degree as the Conners 3-P. Additionally, there is little independent validation of the Conners 3-T, aside from the data put forth by the instrument authors.

Because of the overlap between behaviors – particularly externalizing ones – associated with ADHD and those associated with autism spectrum disorders, it is helpful to understand the function of the Conners 3-T. Also, since autism spectrum disorders sometimes coexist with intellectual disabilities (ID), it is important to understand how the psychometric properties of the Conners' tests hold up among children with ID. Deb et al. (2008) undertook this research with the CPRS-R and the CTRS-R and found that parents and teachers differed significantly in how they rated children with ID (whereas significant correlations between their reports would be expected, based on previously published psychometric data). Also, the authors noted that some of the items were not applicable to children with severe or profound ID, and/or who were nonverbal (as are some children with autism spectrum disorders). These findings have implications for using the Conners' tests to assess children with known autism spectrum disorders and ID.

[Informed consent](#)

Definition

In General

Consent is a voluntary agreement to participate in medical treatment, procedure, or research. A physician or other health care provider must obtain the consent of the patient or of someone legally authorized to give consent for the patient before initiating such activity.

This requirement is based on the principle that every individual of sound mind has a right to determine what shall be done with his own body and to control the course of his medical treatment.

Standard

The historical standard for legally sufficient disclosure was the customary disclosure practices of physicians in the community. The current standard, however, is a more patient-oriented one. It focuses on what material information about risks a reasonable physician would believe a reasonable patient would want to know to make a decision. It thus remains objective, but with due regard for both the patient's informational needs and physician's situation.

Current Law

General principles of consent are the same in all jurisdictions, though specific details of the doctrine may vary. The right of consent requires several elements, including capacity (the patient is competent to make decisions), information (the patient is informed of the benefits and risks), and voluntariness (the patient is not coerced into giving consent). Consent to medical treatment can be oral or written, express, or implied. In some jurisdictions, statutes specify the form that a patient's consent must take. Consent is generally not required in certain circumstances, including emergencies, therapeutic privilege, when the patient is incompetent, and when the patient waives having to consent.

A physician's failure to obtain consent from a patient prior to medical treatment can serve as a factual predicate to a malpractice action.

ASD Application

Patients with developmental disabilities, such as ASD, may have cognitive, social, and mental impairments that limit their ability to provide legal consent.

Minors generally cannot give consent. Instead, parents or legal guardians must give consent, preferably with the child's assent when feasible.

Consequence-Based Interventions

Rebecca Munday

The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Consequence-based interventions are implemented in response to inappropriate behaviors. These interventions are designed to decrease the future likelihood of the inappropriate behavior occurring. Interventions are determined based on the results of a functional behavior assessment. For a consequence-based intervention to be successful, it must be in response to the function of the behavior. Often, antecedent and consequence-based interventions are used in combination to decrease the probability of inappropriate behavior occurring in the future. Some examples of consequence-based interventions are differential reinforcement and its variants, extinction, response cost, and redirection.

Conservatorship

► [Guardianship](#)

Conservatorship (Full Conservatorship and Limited Conservatorship)

Annemarie M. Kelly and
Christina N. Marsack-Topolewski
College of Health and Human Services, Eastern
Michigan University, Ypsilanti, MI, USA

Definition

A conservatorship is a legal relationship in which a court gives one person, a conservator, the duty and power to make decisions about financial and property matters for the benefit and protection of a beneficiary (also referred to as a person subject to conservatorship) (Garner 2014).

Principles of Conservatorship

Conservatorships can be a useful special needs planning tool for individuals with autism spectrum disorder (ASD) and their caregivers (Werner & Chabany 2016). The term “conservator” is generally understood as a guardian, protector, or preserver of another person’s property. State courts have jurisdiction in conservatorship matters to protect individuals who are unable to care for their estate because of a severe impairment or disability (Uniform Law Commission, 2007, 2017). A conservatorship beneficiary’s estate includes all personal assets, real property, and funds. Beneficiaries can be minors or adults.

Each conservatorship must be appointed by a judge. A court order authorizes a conservator to manage and safeguard a beneficiary’s estate. Conservators are legally required to act in a beneficiary’s best interests at all times (Devi 2013). Depending on the scope of a judge’s conservatorship order, a conservator’s scope of authority can be broad and include such matters as deciding an individual’s spending priorities, budgets for activities, and trust savings allocations.

In the United States, conservatorship decision-making laws contain three key principles:

1. Ensuring that a conservatorship is invoked only as a last resort and after considering the availability of support to assist people with financial decision-making.
2. Ensuring a conservatorship is as confined in scope and duration as is reasonably possible.
3. A conservator’s decision-making should always respect the will, preferences, and rights of the individual beneficiary (National Council on Disability 2018).

Conservatorship Terminology

In the past, the terms “ward,” “incompetent person,” and “incapacitated person” were regularly used to describe a person with a conservatorship. Today, there is a growing movement among disability rights advocates to discard these terms as outdated, derogatory, and disrespectful. Modern terminology in conservatorship cases increasingly emphasizes the importance of each individual’s right to self-determination and general autonomy (Page & Hinrichs 2017). When describing a person who receives conservatorship services, the following terms are widely used: beneficiary, conservatee, individual subject to conservatorship, adult who is the subject of a conservatorship proceeding, protected individual, protected person, and principal (Dinerstein 2012).

Conservatorships are largely governed by the probate laws of the individual states. The title of conservator is not used consistently across all state codes, and a conservator’s requirements and functions can differ greatly among state laws. Though a small number of state laws consider the term “conservatorship” a synonym for a “guardianship,” the majority of states do not use the words interchangeably (Kohn et al. 2013). As a general rule, a guardian’s decision-making abilities include decisions about both personal well-being and financial/property interests. In contrast, a conservator’s decisions are limited to only financial/property matters (National Council on Disability 2019).

In most states, there are two types of conservatorships: full and limited (American Bar Association Commission on Law and Aging 2016). A full

conservatorship is designed to care for all of the essential elements of a beneficiary's estate. If an individual's circumstances do not require a full conservatorship, a judge may decide to order a limited conservatorship (also known as a partial conservatorship). In limited conservatorship cases, a conservator has a narrow scope of work in matters related to a beneficiary's estate – these conservators can only make decisions about specific situations regarding the beneficiary's property matters (Wilber et al. 2001). In some states, the title of "custodianship" is used to describe a full conservatorship or various types of conservatorship with limited authority.

Legal Capacity in Conservatorship Cases

Before issuing a court order to appoint a conservator, a judge must first declare that a beneficiary lacks "legal capacity (Parker 2016). Historically, the term legal capacity was also referred to as "legal competency." Individuals do not have legal capacity when they are deemed entirely incapable of managing financial affairs. In these instances, the individual is unable to fully safeguard himself or herself against harm to personal wealth and/or property. A judge will determine that a beneficiary lacks legal capacity based on evidence presented to the court, including medical records and testimony from treating physicians, mental health professionals, caregivers, family members, friends, and the individual under review for the conservatorship appointment (United States General Accounting Office 2004).

For a conservatorship appointment, a beneficiary's legal capacity must be distinguished from his or her mental ability (Dudley & Edmonds 2018). Legal capacity embodies individual legal rights to have standing to bring and defend lawsuits and enter into/execute legally binding contracts. In contrast, mental or cognitive capacity issues in conservatorship matters focus on a person's ability to express personal will and intentions. Depending on the jurisdiction in question, state law may require conservators to take a beneficiary's preferences into account when

making life-changing decisions about finances and property (Kohn & Blumenthal 2014).

Under all state laws, if the circumstances that originally mandated a conservatorship have materially changed, courts are obligated to perform a review to confirm whether the conservatorship is still required or if another type of protective measure is more appropriate.

Starting a Conservatorship

When a judge considers whether a conservatorship appointment is necessary, the court may proceed with the following steps:

1. Hold an evidentiary hearing.
2. Order individuals produce evidence or give testimony (including the proposed beneficiary under review for a conservatorship, health-care treatment providers, family members).
3. Order a medical evaluation or assessment of the proposed beneficiary's abilities and impairments.
4. Order any appropriate investigation of any proposed conservator or other individuals involved in a conservatorship proceeding.
5. Review a certified copy of the transcript or other hearing records of from conservatorship proceedings in other courts.
6. Issue an order authorizing the release of medical, financial, criminal, or other relevant information, including protected health information subject to state and federal privacy laws for records.

Ending a Conservatorship

There are two ways to end a conservatorship: with a court order or when the beneficiary passes away. When the beneficiary dies, his or her conservatorship terminates automatically. If a conservator's assistance is no longer needed because of a significant change in the beneficiary's cognitive and/or physical state, the court may decide to formally terminate the conservatorship. Anyone who is interested in the beneficiary's welfare can

petition a court to end a conservatorship, including the conservator, a family member, friend, or the beneficiary himself or herself. Upon this petition, a judge will decide whether a conservatorship should: (1) continue as is, (2) be modified to limit the conservator's responsibilities, or (3) end (Uekert et al. 2018). Ultimately, a judge will consider what is in the best interest of the beneficiary and only deem a conservatorship inappropriate when there is enough evidence in the court's records to show that a "good cause" exists for termination.

If a conservator wishes to resign from his or her appointment, a judge must file a resignation request with the court. Before a judge approves a conservator's resignation request, the judge will appoint another person to serve as conservator (Van Arsdale & Oakes 2020).

Constipation

Koorosh Kooros

Pediatric Gastroenterology and Nutrition, Rady Children's Hospital, San Diego, University of California San Diego, San Diego, CA, USA

Synonyms

Dyschezia; Fecal impaction; Obstipation

Definition

The definition of constipation varies among individuals. To some, it is hard stools; to others, it is large stools; and to many more, it is infrequent stools. Because the word “constipation” has different meanings for different people, it has been difficult to compile data on normal and abnormal patterns in children (Schuster 1984). Webster's English Dictionary reads “a term used to describe the subjective complaint of passage of abnormally delayed or dry, hardened feces, often accompanied by straining and/or pain” (Webster's ninth new collegiate dictionary 1986). Guidelines of the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) similarly define constipation as “a delay or difficulty in defecation, present for 2 or more weeks and sufficient to cause significant distress to the patient” (Baker et al. 1999). At present, the most widely accepted definitions for childhood functional constipation are the Rome III definitions (Hyman et al. 2006 and Rasquin et al. 2006) (12,13). An evidence-based recommendations from ESPGHAN (European Society of Pediatric Gastroenterology, Hepatology and Nutrition) and NASPGHAN in 2014 defined constipation as follows (Tabbers et al. 2014).

In the absence of organic pathology, two of the following must occur:

For a child with a developmental age < 4 years

1. ≤ 2 defecations per week
2. At least 1 episode of incontinence per week after the acquisition of toileting skills

3. History of excessive stool retention
4. History of painful or hard bowel movements
5. Presence of a large fecal mass in the rectum
6. History of large-diameter stools that may obstruct the toilet

Accompanying symptoms may include irritability, decreased appetite, and/or early satiety, which may disappear immediately following passage of a large stool.

For a child with a developmental age 4 years with insufficient criteria for irritable bowel syndrome

1. ≤ 2 defecations in the toilet per week
2. At least 1 episode of fecal incontinence per week
3. History of retentive posturing or excessive volitional stool retention
4. History of painful or hard bowel movements
5. Presence of a large fecal mass in the rectum
6. History of large-diameter stools that may obstruct the toilet

One can conclude then that normal stool frequency ranges from an average of four per day during the first week of life to two per day at 1 year of age. The normal adult range of three per day to three per week is attained by 4 years of age. These data reflect the average stool frequency in normal infants and children in industrialized countries, not in developing countries, where the normal diet is rich in fiber and normal stool frequency may be different.

Many experts believe that constipation is the delay in defecation for approximately 2 weeks or difficulty in defecation. The causes of constipation are many and may be organic or nonorganic; medications can be a potential cause. Children with ASDs can have sensory processing abnormalities and develop stool-withholding behaviors or constipation related to altered pain responses. Even children with ASDs who have daily bowel movements may have retention of stool that is not evident to parents, teachers, or health-care providers (Buie et al. 2010).

Estimates suggest that ~95% of childhood constipation may be functional, without an

underlying physiologic cause, and many children with ASD present with nonorganic toileting problems that may precipitate or play a role in the development of constipation, including absent or delayed acquisition of bowel training (Whiteley 2004) and higher rates of problem behaviors related to changes in toileting routine. Fecal retention in ASD may also occur secondary to difficulty with sensory stimuli, sensory processing, and motor problems, leading to altered gastrointestinal motility and defecation physiology (Peeters et al. 2013). It is also possible that elevated rates of constipation may be related to the ubiquity of food selectivity in this population, as the dietary patterns often associated with ASD involve high intake of processed food and lack fiber-containing fruits and vegetables, which provide a natural laxative effect and decrease intestinal transit time.

The evaluation of all children who present with constipation should include a thorough medical history and physical examination. Understanding what the family or child means when they use the term “constipation,” the frequency of bowel movements, the consistency and size of stool, and the presence or absence of abdominal pain is important. A history of stool-withholding behavior points more toward functional causes of constipation. For children with ASDs, the physical examination may not identify palpable stool, and a careful rectal examination might not be feasible. Every attempt should be made to examine the rectum, although at times it cannot be accomplished. The rectal examination enables the assessment of stool retention, anal tone, and occult mass, as well as the presence or absence of blood, and helps to reassure the family that the child’s anatomy is normal. A plain radiograph of the abdomen may reveal a rectal fecal mass not palpable on the abdominal examination, but due to conflicting evidence for the accuracy of radiologic diagnosis of constipation, routine radiography is not recommended. Diagnostic clues can help to identify some organic causes of constipation. Hirschsprung’s disease is common in children with ASDs, and a history of delayed passage of stool after birth should raise

the suspicion of aganglionosis. Anatomic abnormalities such as an anterior displacement of the anus, which is more common in girls than boys, can be diagnosed by careful inspection of the anal area. Drugs added to behavior management for constipation are often beneficial. Mineral oil, magnesium hydroxide, lactulose, sorbitol, polyethylene glycol (PEG), or a combination of lubricant (mineral oil) and laxative is recommended for the daily management of constipation in children.

► Itinerant Teacher

Contactin-Associated Protein 2

John D. Murdoch

Child Study Center, Yale University School of Medicine, New Haven, CT, USA

The gene CNTNAP2 encodes the protein *contactin-associated protein-like 2* (recommended UniProt name; also known as Caspr2), a member of the neurexin superfamily, and of a class of genes functioning in the nervous system as cell adhesion molecules and receptors acting at the cell membrane ([EntrezGene](#)). This gene is less frequently referred to as AUTS15, CDFE, CASPR2, PTHSL1, NRXN4, KIAA0868, and DKFZ-p781D1846 ([UniProt](#); [BioGrid](#)).

Structure

CNTNAP2 is located at chromosome 7q35; the genic region of this gene is quite large, spanning 2.3 MB (Nakabayashi and Scherer 2001). In humans, there is a single established isoform (or version of the gene) consisting of 24 exons. The final protein product is 1,331 amino acids. The protein spans the cell membrane one single time ([UniProt](#)). The protein consists, in order, of a signal peptide (a short sequence directing the protein product where to go in the cell), a FA58C domain (“cell surface-attached carbohydrate-

binding domain”), two laminin G domains (common in extracellular proteins), an epidermal growth factor-like domain (also frequently found in extracellular proteins), a fibrinogen C-terminal domain, another laminin G domain, another epidermal growth factor-like domain, another laminin G domain, a helical transmembrane domain (spanning the membrane between the inside and outside of the cell), and a cytoplasmic domain (the only portion of the mature protein that is inside the cell). This transmembrane and cytoplasmic end of the protein also contains a putative band 4.1 homologues’ binding motif (common to neurexins as well as syndecans and glycophorin C intracellular C-termini, all of which are cell surface proteins) ([SMART](#); [UniProt](#)).

Function

CNTNAP2 was first described by Poliak, Gollan, Martinez, et al. (1999) and was shown to be a member of the neurexin superfamily that localized within juxtaparanodal regions of myelinated axons and clustering with potassium channels. The juxtaparanode is the region next to the paranode, which is on either side of the node of Ranvier, an unmyelinated (unsheathed) region of the axon that allows for efficient signal conduction. Homologs of CNTNAP2 are found as far back as insects (*D. melanogaster*, *A. gambiae*) and nematodes (*C. elegans*) ([EntrezGene](#)), further implying important neural function. CNTNAP2 was shown to interact with CNTN2 (TAG-1); in the absence of CNTN2, CNTNAP2 failed to localize at juxtaparanodes and potassium channels did not accumulate normally (Traka et al. 2003). The transcription factor FOXP2, itself implicated in language function ([EntrezGene](#)), was shown by Vernes, Newbury, Abrahams, et al. (2008) to directly regulate CNTNAP2 expression. CNTNAP2 was also shown to have higher expression in circuits involved in higher cortical function, like language (Abrahams et al. 2007). A recent mouse knockout (an animal in which both copies of a gene have been removed) of CNTNAP2 showed dysfunction in neuronal migration (ectopic neurons occurring in the corpus callosum) and reduced numbers of

interneurons (Peñagarikano et al. 2011). One study has shown evidence of CNTNAP2 in rat forebrain synapses (Bakkaloglu et al. 2008), but it has not been definitively characterized as a synaptic molecule.

Pathophysiology

CNTNAP2 has been implicated in several psychiatric disease phenotypes, including Tourette syndrome and obsessive-compulsive disorder (Verkerk et al. 2003), but has received particular attention for its possible association with autism. Initially, linkage evidence suggested a language-linked gene on chromosome 7q35 (Alarcon et al. 2002, 2005). A homozygous mutation in CNTNAP2 was associated with a cortical dysplasia and focal epilepsy phenotype, resulting in seizures, language and social impairments, mental disability, and autistic traits (Strauss et al. 2006). CNTNAP2 was additionally implicated in multiplex autism families by a linkage peak at 7q35 and showed subsequent significant association with a single DNA base change, or single nucleotide polymorphism (SNP) within the gene in an analysis of parent-affected child trios (Arking et al. 2008). A fine-scale analysis of the 15 mb region (7q34-36) encompassing the implicated 7q35 language region in 172 parent-autistic child trios reinforced CNTNAP2 as an autism candidate gene; follow-up analysis in 304 separate parent-autistic child trios showed association of a SNP in CNTNAP2 with age at first spoken word, again underscoring a possible connection to language phenotype as suggested by Vernes et al. (2008). Parallel work in this study showed CNTNAP2 expression very specific to brain circuits established as essential for executive function in humans (Alarcon et al. 2008). Also in 2008, large-scale resequencing of the CNTNAP2 gene in 635 autism cases and 942 unaffected controls showed overrepresentation of rare deleterious (i.e., changing the amino acid in a way that is predicted as harmful) mutations in autistic patients compared with unaffected controls, but not at a statistically significant level. A specific mutation, I869T (the 869th amino acid changed from isoleucine to threonine), however, occurred four times in

three unrelated families and was not seen in any controls, reaching statistical significance. In each case, it was inherited from an ostensibly unaffected parent, suggesting again that idiopathic (nonsyndromic) autism may sometimes involve harmful mutations in multiple neurological genes at once. A 2010 study described two siblings with a deletion spanning CNTNAP2 who showed mental retardation and language delay (Sehested et al. 2010); a separate study described a boy with a complex chromosomal rearrangement (pieces of chromosomes breaking off and rearranging spontaneously) disrupting CNTNAP2 who presented with speech delay and ASD (Poot et al. 2010). More recently, a rare, predicted deleterious CNTNAP2 variant was observed when 20 exomes of patients with autism were sequenced (O’Roak et al. 2011), perhaps acting in concert with a FOXP1 mutation in that patient. Finally, a report of a mouse model with both copies of the mouse homolog of CNTNAP2 knocked out (Peñagarikano et al. 2011) described mice with deficits in the 3 ASD core features, in addition to epileptic seizures (reminiscent of Strauss et al. 2006) and hyperactivity. The evidence in CNTNAP2 to date, as well as the implication of several other neurological genes (e.g., NLGN3, NLGN4 X-linked, SHANK3, NRXN1) involved neuron and synapse structure and development, means that further research on CNTNAP2 will undoubtedly continue and, hopefully, better elucidate its precise role(s) in autism spectrum disorders.

Contingencies of Reinforcement

Dennis Mozingo

Integrated Behavioral Solutions, Atlanta,
GA, USA

Definition

Contingencies of reinforcement, in their simplest form, are comprised of antecedents (events that occur immediately before a behavior), responses or behaviors, and consequences (events that occur immediately after a behavior). The term *contingencies* refers to the relationship or interrelationship (Skinner 1969) between these events. *Reinforcement* refers to consequences that increase the probability of the behavior occurring again under similar circumstances. Thus, contingencies of reinforcement describe an antecedent-behavior-consequence link in which the consequence increases the likelihood that a behavior will occur again in the presence of an antecedent. Contingencies of reinforcement are a key component in applied behavior analysis (ABA) approaches to the treatment of autism spectrum disorders (ASD). For example, discrete trial teaching includes the presentation of an antecedent (an instruction, often referred to as a *discriminative stimulus* when it comes to occasion a specific response under specific conditions), the learner’s response, and the presentation of reinforcement. In the case of teaching verbal (or social) behavior with learners with ASD,

written or pictorial rules may be used for effectively initiating a social greeting. The rules serve an antecedent function that may occasion the behavior, in the absence of a history of reinforcement. When the behavior is exposed to naturally occurring contingencies, such as a smile in response to eye contact, a shaping process may occur, leading to behavior shaped (better eye contact during a greeting) and maintained by the contingencies of reinforcement, rather than the rule. The behavior required by the rule must be maintained by consequences (part of the contingency) to be effective – an effective rule is supported by the contingencies of reinforcement.

Contingency Contracting

Solandy Forte
The Center for Children with Special Needs,
Glastonbury, CT, USA
Milestones Behavioral Services, Inc., Milford,
CT, USA

Definition

A contingency contract is a positive intervention that specifies the behavioral, social, or academic

expectations to be completed in order to access reinforcement. A contract is typically developed by the practitioner providing treatment in collaboration with the client or stakeholders. A clear definition of the task(s), to be completed by the client(s), is outlined, a criterion is established, and a reinforcer is identified. The contract will also monitor individual or group progress after obtaining the baseline level of performance. The implementation of these contracts can target one or more behaviors that are client or group specific. An example of a contingency contract is a token economy system which specifies the target behavior to increase, tokens to be delivered, and the reinforcer as secondary for exhibiting the target behavior and also specifies a variety of highly preferred reinforcers to earn in exchange for the tokens. Contingency contracts are widely used across a variety of settings including home, community, classroom, and clinical settings.

Continuous Data Collection

Shaunessy Egan and Katelyn Herchel
Center for Children with Special Needs,
Glastonbury, CT, USA

Synonyms

[Continuous measurement](#); [Continuous recording](#)

Definition

Continuous data collection involves methods in which data are collected on all occurrences of behavior during behavioral observations or programmed learning opportunities. When employed during behavior observations, continuous data collection requires the recording of all instances of the response class(es) of interest. When employed during discrete trial training, continuous data collection requires the recording of learner responses and/or prompt levels for each learning trial. Continuous data collection is considered more comprehensive and precise when compared to discontinuous data collection; however, it is also regarded as less practical when available resources preclude recording each instance of the behavior.

Conversational Manner

Sarita Austin
Unlocking Language, London, UK

Definition

Conversational manner refers to the extent to which an individual is able to avoid ambiguity and make clear, concise, and orderly contributions to conversation. The maxim of manner is one of four conversational maxims (general truths or rules of conduct) that guide cooperative conversation in everyday life, as identified by the twentieth-century

linguistic philosopher, Herbert Paul Grice. The other three conversational maxims include the maxims of quality (providing truthful information), quantity (providing sufficient, but not excessive information), and relation (providing relevant information). Failure to adhere to one of these maxims in conversation may lead to the communication breakdowns, such as those that often occur with individuals with autism spectrum disorders (ASD) during discourse. The following response would be considered a violation of the maxim of manner as it lacks clarity as a choice between options has not been made.

Question: Do you want a pepperoni or plain slice?
 Answer: Maybe I'll have the pepperoni or a plain slice.

Alternatively, purposeful violations of a maxim may create what Grice called "implicature," the use of the violation to convey a message that differs from the literal content of the utterance. For example, a young man who violates the maxim of manner when asked about a meeting location by saying "I've been to every last spot in this town and realize that there is not one cool place to hang out. And you know how it is having friends over when you have strict parents" forces his classmate who asked him, "Do you want to hang out with me?" to consider that while, on the surface, he has not clearly answered her question, the implicature she is to draw is that he means that he does not want to hang out with her and is offering a long and vague response in order to avoid directly saying "no" and embarrassing or hurting her.

The existing literature on language use and conversational skills in individuals with ASD indicates that appropriately modifying conversational manner based on listener and context may present a challenge in this group. Individuals with ASD may present ambiguous or disorganized statements without taking into account the interests or knowledge of their listeners.

CNVs

Definition

Copy number variations (CNVs) are deleted or duplicated segments of the genome, typically defined as including ≥ 1000 base pairs of DNA. Deletions and duplications smaller than this are called “indels.” The presence of CNVs in phenotypically normal individuals was not appreciated until 2004 with landmark papers by Iafrate and Sebat (Iafrate et al. 2004; Sebat et al. 2004). Like single-nucleotide polymorphisms (SNPs), CNVs are part of the normal variation between two individuals and may either be inherited from parents or appear de novo. A recent effort to map of CNVs across the human genome (Zarrei et al. 2015) estimated that between 4.8 and 9.5% of the genome varied due to CNVs in healthy individuals, with the number of CNVs falling between roughly 11,500 and 24,000.

The importance of CNVs for ASD was first noted in 2007 by Sebat (Sebat et al. 2007). This study focused on large de novo CNVs (i.e., not present in either parent). These large de novo CNVs were found to be more common in children with autism compared to children without. In this

initial study, the authors also demonstrated an increased rate of de novo CNVs in simplex autism families compared to multiplex autism families. This finding has been replicated multiple times (e.g., Marshall and Scherer 2012; Iossifov et al. 2014 and Sanders et al. 2015) with estimates of ASD risk contribution from over 200 de novo CNVs ranging from approximately 4% to 8%. Recent evidence suggests that small de novo deletions tend to impart risk through the disruption of one major risk gene (as opposed to large CNVs which contribute risk by disrupting multiple genes in parallel). Excitingly, this insight means that small de novo CNVs can be used to enhance the discovery of ASD risk genes (Sanders et al. 2015). Finally, though the vast majority of genetic risk for ASD comes from inherited mutations (Gaugler et al. 2014), the overall contribution of inherited CNVs (both rare and common) has yet to be definitively characterized. However, evidence to date suggests that *rare* inherited CNVs contribute modest risk only (Sanders et al. 2015).

Since the recognition of CNVs’ importance in ASD, multiple studies have aimed to identify specific regions of DNA in which they contribute risk. The best characterized CNVs include 16p11.2 which has been found in 1% of children with autism compared with $<0.1\%$ in unaffected individuals, as well as 15q12, 15q11.2–13.1, 1q21.1, and 2p16.3. Interestingly, some CNVs seem to carry much greater risk as deletions (2p16.3) or duplications (15q12, 15q11.2–13.1, 1q21.1); however others, notably 16p11.2, demonstrate a more balanced split between both cases.

Cornelia de Lange Syndrome

Elizabeth A. DeLucia

Yale Child Study Center, New Haven, CT, USA

Virginia Polytechnic Institute and State

University, Blacksburg, VA, USA

Synonyms

[Brachmann-de Lange Syndrome](#); [CdLS](#); [de Lange Syndrome](#)

Cornelia de Lange Syndrome (CdLS) is a rare developmental disorder. It was first described by Dutch pediatrician Cornelia de Lange in 1933. Prevalence estimates of CdLS range from 1 in 10,000 births to 1 in 100,000 births. The syndrome is characterized by distinctive facial features, including thick eyebrows that meet at midline, long eyelashes, low-set ears, an upturned nose, a long, smooth philtrum and thin upper lip. CdLS is also associated with small head circumference, in addition to slowed growth before and after birth. Most affected individuals remain below the 5th percentile on the growth curve throughout their lives, and CdLS-specific growth curves have been created for this reason. CdLS patients also typically present with limb abnormalities, ranging from small hands to the absence of forearms, and hirsutism. Intellectual disability is characteristic of CdLS, although individuals with a milder phenotype of the syndrome may present with IQs in the normal range. Reported IQs of affected individuals range from 30 to 102, with an average IQ of 53. Individuals with CdLS usually have gastroesophageal reflux and can present with a variety of other gastrointestinal problems. The majority of children with CdLS experience sensorineural hearing loss. Seizures have been noted in approximately 25% of affected individuals.

Approximately 60% of CdLS cases are attributable to mutations in the NIPBL gene, located on chromosome 5. An additional 10% of CdLS cases

can be attributed to mutations on one of the following genes: SMC1A, HDAC8, RAD21, and SMC3 (accounting for roughly 5%, 4%, <1%, and 1–2% of cases, respectively). In the remaining 30% of cases, the cause of CdLS is unknown. Ninety-nine percent of cases of CdLS come from de novo mutations. A diagnosis of CdLS is established based on the identification of one of the above variants or based on clinical presentation consistent with the syndrome.

Treatment for CdLS varies based on the symptoms with which each patient presents. Gastrointestinal intervention is often required to treat severe gastroesophageal reflux or intestinal malrotation. If limb abnormalities hinder functioning, surgical intervention can be considered. Additionally, physical, speech, and occupational therapies may be utilized in order to optimize developmental outcomes. For individuals who are nonverbal or minimally verbal, alternative communication methods and devices such as PECS and sign language can be used. When hearing loss and seizures occur, they are addressed using standard treatments.

Many individuals affected by CdLS experience autism-like symptoms and self-injurious behavior. Studies have found ASD prevalence among individuals with CdLS ranging from 43% to 85%. There is some thought that the social and communication deficits associated with CdLS are related to high levels of social anxiety among those affected. To date, the literature has not examined whether traditional treatments for ASD are effective in individuals with comorbid ASD and CdLS.

[Colossal commissure](#); [Interhemispheric white matter tract](#)

Definition

The corpus callosum (CC) is the largest interhemispheric fiber tract of the human brain, consisting of more than 200 million neural fibers that connect homologous (i.e., similar) and heterotopic (i.e., different) regions across the left and right hemispheres. The CC is typically divided into subregions from anterior to posterior using either a three-region or seven-region system. Table 1 presents the three broad subregions and a commonly used seven region subdivision scheme by Witelson (1989), either of which may be used to refer to subregions of the CC. The Witelson scheme, which is often used in research studies, includes seven specific subdivisions: the rostrum, genu, rostral body, anterior midbody, posterior midbody, isthmus, and splenium.

Corpus Callosum, Table 1 Common subregions or segments of the corpus callosum

Region	Anatomical label	Cortical region(s)
Broad regions		
Anterior	Frontal lobe	Prefrontal cortex
Body	Frontal, parietal lobes	Premotor, supplementary motor, sensory, and posterior parietal cortex
Posterior	Temporal, parietal, occipital lobes	Superior and inferior temporal, posterior parietal, visual and secondary occipital cortex
Witelson regions		
1	Rostrum	Caudal/orbital prefrontal, inferior premotor
2	Genu	Prefrontal
3	Rostral body	Premotor, supplementary motor
4	Anterior midbody	Motor
5	Posterior midbody	Somesthetic, posterior parietal
6	Isthmus	Superior temporal, posterior parietal
7	Splenium	Occipital, inferior temporal

Corpus Callosum, Fig. 1 From anterior to posterior, the Witelson (1989) subdivisions include the rostrum (*black*), genu (*yellow*), rostral body (*pink*), anterior midbody (*aqua*), posterior midbody (*green*), isthmus (*deep blue*), and splenium (*red*)

The CC is topographically organized with specific regions connecting fibers originating from defined brain regions (Fig. 1). For example, fibers originating in prefrontal cortex cross the CC in the genu, while fibers starting from the occipital and inferior temporal regions cross at the level of the splenium (Hofer and Frahm 2006). These regions of the CC contain connecting fibers important for many different cognitive functions including attention, memory, language, and other specific abilities. Developmentally, the CC shows an inverted

U-shaped pattern with early increases in volume and integrity through adolescence and early adulthood, followed by later reductions (Giedd et al. 1999; Hasan et al. 2009). Based on its anatomy and functional roles, the CC has been conceptualized as an index of the development of structural and functional connectivity of the hemispheres including aberrant connectivity in neuropsychiatric disorders such as autism (Vidal et al. 2006).

Relevance to ASD

Many research studies have investigated the size of the CC and its segments in autism (see reviews Frazier and Hardan 2009; Lefebvre et al. 2015). The most consistent finding has been a general reduction in the size of the CC in individuals diagnosed with ASD, especially when CC size is considered in relation to total brain volume. Studies that have investigated the size of the CC subregions in ASD have reported somewhat variable results in terms of the subdivisions that are smaller in comparison to controls; however, it appears that the anterior and posterior subdivisions that carry interhemispheric projections from the prefrontal/premotor and posterior parietal areas may be the most affected. This observation, as well as the role of the CC in connecting many brain networks, has provided impetus for further investigation into abnormalities of the interhemispheric pathways

in ASD, especially regarding the hypothesis of abnormal network connectivity in autism (Belmonte et al. 2004). Additionally, a recent longitudinal study that assessed young infants at high-risk for later diagnosis of ASD (6 months, 12 months, and 24 months) suggested that the developmental trajectory of the CC may be altered in ASD (Wolff et al. 2015). Developmental changes were observed in this study with CC thickness being greater during the early postnatal period before a period of relative “normalization” at 24 months. These alterations might precede the abnormalities reported in older children and adults, including the reduction in CC size. Clearly, continued research into the developmental trajectory of the CC in ASD is warranted.

Furthermore, individuals with complete or partial absence of the corpus callosum as a result of abnormal development (agenesis) may exhibit social and communication deficits that result in a diagnosis of ASD in these individuals (Paul et al. 2007). However, agenesis of the corpus callosum is not a characteristic or common finding in ASD and is part of many other congenital syndromes with a wide range of etiologies, including fetal cytomegalovirus infection. The basis of the clinical overlap between ASD and agenesis of the corpus callosum and vice versa is currently under investigation.

Definition

Corpus callosum (CC) abnormalities in autism spectrum disorder (ASD) generally refer to reductions in the midsagittal size, volume, or integrity of the CC in individuals affected by this disorder.

Historical Background

Over the last few decades, case reports have been published supporting an association between partial or complete agenesis or other abnormalities of the CC and social deficits. While not all individuals with agenesis of the corpus callosum meet full DSM criteria for autism spectrum disorder, they often show behavioral, cognitive, and functional patterns reminiscent of autism, particularly individuals with complete agenesis (Paul et al. 2007).

The first careful examination of the CC in autism using magnetic resonance imaging was published by Gaffney et al. (1987). This study did not identify significant differences in midsagittal CC area. However, the lack of significant findings was likely due to a small sample size and the limitation of the early morphometric neuroimaging methodologies. Indeed, following this initial investigation, a series of studies have reported reductions of CC size examining a wide age range of individuals with autism and varying levels of cognitive abilities (Hardan et al. 2000; Just et al. 2007; Manes et al. 1999; Piven et al. 1997; Vidal et al. 2006). For example, studies by Piven et al. (1997) and Hardan et al. (2000) identified reduced midsagittal area of the CC in individuals with ASD. Based on these preliminary investigations, the first meta-analysis of CC size in ASD (Frazier and Hardan 2009) was completed and included ten total studies published between

1987 and 2007, which examined both the total CC and Witelson subdivisions (see Fig. 1 below). Although three of the ten studies conducted over this time period did not find a significant reduction of the CC in autism, when considered together, this pool of studies identified a highly significant reduction of the overall CC in ASD. Additionally, this meta-analysis found that the largest reduction occurred in a subdivision of the CC called Witelson subdivision 3: Rostral body, which is important for motor planning and also includes mirror neurons crucial to representing others' behavior (see Fig. 1 in the Definition of the Corpus Callosum for a view of the whole CC and Witelson subdivisions).

Since the first meta-analysis of CC size in ASD (Frazier and Hardan 2009), 11 additional investigations have been conducted, which largely support a reduced size of the CC in ASD (Alexander et al. 2007; Anderson et al. 2011; Casanova et al. 2011; Frazier et al. 2012; Freitag et al. 2009; Hardan et al. 2009; Hong et al. 2011; Keary et al. 2009; Nordahl et al. 2015; Prigge et al. 2013; Tepest et al. 2010). Two studies conducted during this time failed to find any indication of altered CC size in ASD (Tepest et al. 2010; Hong et al. 2011); however, one study focused only on individuals that received a diagnosis during adulthood (Tepest et al. 2010) and the other reported a significant reduction in density of the CC (Hong et al. 2011), which is also supported by other related studies (Chung et al. 2004; Kumar et al.

Corpus Callosum Abnormalities in Autism,

Fig. 1 The magnitude of reductions in the total CC and Witelson subdivisions in individuals with autism. Witelson subdivision 3: rostral body shows the largest reduction

2010; Spencer et al. 2006; Waiter et al. 2005). A new meta-analysis that included the majority of these additional studies was published in 2015 (Lefebvre et al. 2015) and generally supported a reduction in CC size across these investigations, albeit with additional considerations regarding limitations of these previous studies. Following the updated meta-analysis, Lefebvre et al. (2015) also examined CC size in the largest ASD cohort to date, the Autism Brain Imaging Data Exchange (ABIDE), which included 328 patients with high-functioning ASD and 366 controls (7.5–40 years old). Although they failed to find a reduction of CC size in ASD, confounding factors such as participant age, sex, cognitive functioning level, and scanning site may have contributed. Additionally, there appeared to be potential interactions between ASD diagnosis and total brain volume and IQ, suggesting other factors may have contributed to the previously reported group differences or the lack thereof in the ABIDE investigation.

Further supporting CC abnormalities in ASD, diffusion tensor imaging investigations have examined water diffusivity in the CC and generally suggest structural alterations indicative of white matter abnormalities, such as lower fractional anisotropy or higher diffusivity (Alexander et al. 2007; Barnea-Goraly et al. 2004; Hong et al. 2011; Jou et al. 2011a, b; Keller et al. 2007; Kumar et al. 2010; Mengotti et al. 2011; Shukla et al. 2010; Travers et al. 2015) and reduced tract volume or fiber length (Hanaie et al. 2014; Hong et al. 2011; Thomas et al. 2011). These alterations may be due to reductions in the number of axons traveling between hemispheres (hypoplasia) rather than loss of axon integrity or atrophy (Chung et al. 2004); however, a magnetization transfer scan study also reported potentially abnormal myelination of the CC in ASD as well (Gozzi et al. 2012). Overall, it appears that a reduction in CC size and abnormal white matter quality are generally supported in ASD, especially in childhood and adolescence; however, additional research will be necessary to determine the developmental trajectory of CC in individuals with ASD during perinatal development and early infancy.

Current Knowledge

The localization of the exact CC structural abnormalities in ASD has been more thoroughly examined recently. While most studies reported reductions in the total size of the CC, some investigations have suggested that this reduction may be most pronounced in the anterior and posterior subdivisions (Chung et al. 2004; Frazier et al. 2012; Hardan et al. 2009; Keary et al. 2009; Nordahl et al. 2015; Prigge et al. 2013), which are also supported by diffusion tensor imaging studies (Hanaie et al. 2014; Hong et al. 2011; Jou et al. 2011a, b; Thomas et al. 2011; Travers et al. 2015). These findings suggest corresponding structural alterations in frontal, temporal, and parietal regions, which are consistently reported in the literature, see review (Amaral et al. 2008). This pattern is suggestive of early life abnormalities of the CC in ASD. Interestingly, investigations of the CC in young infants that are later diagnosed with ASD suggest potentially altered developmental trajectories of the CC. For instance, some studies report higher fractional anisotropy and increased thickness of the CC in ASD during early infancy (Weinstein et al. 2010; Wolff et al. 2012, 2015) followed by a potential “normalization” by 24 months of age, which seems to precede the aforementioned reduction in CC size during childhood (2–4 years old; Boger-Megiddo et al. 2006; Nordahl et al. 2015) and into adolescence and adulthood (Hardan et al. 2000; Just et al. 2007). This indicates that early CC abnormalities are present in infants that are later diagnosed with autism but the development of hypoplasia of the CC over time corresponds with the presentation of many autism symptoms (Lord et al. 2008; Piven et al. 1996; Seltzer et al. 2003). This potential early overgrowth followed by a relative reduction in size is reminiscent of the global developmental differences in brain size that have been previously reported in ASD (Courchesne et al. 2001), perhaps on an accelerated time course.

Additionally, updated studies and reviews of small case series or small group studies of individuals with agenesis of the CC without intellectual disability have provided further support for a

relationship between the CC and ASD. These observations suggest not only symptom and behavioral patterns similar to what are seen in individuals with ASD but also alterations in thinking abilities consistent with those seen in this disorder. For example, individuals with agenesis of the CC often show cognitive deficits with problems in abstract reasoning, deciphering nonliteral language (metaphors, idioms, sarcasm, humor), and generalization (Brown and Sainsbury 2000; David et al. 1993; Fischer et al. 1992; Solursh et al. 1965; Williams et al. 2006), similar to what has been observed in individuals with ASD.

Future Directions

Progress has been made to date in understanding the pathophysiology of the CC in ASD, but additional studies examining this structure are needed to identify the underpinnings of CC abnormalities and determine how these abnormalities relate to the core features. Longitudinal studies of young children as they grow may be a particularly powerful way to uncover the pattern of development of the CC and relate these changes over time to autism symptomatology. One such investigation found a persistent reduction in CC volume in children and adolescents with ASD over a 2-year period, except for the rostral body, which exhibited relative “normalization” compared to controls (Frazier et al. 2012). Additionally, future studies should apply multimodal imaging techniques over different developmental periods to provide a comprehensive picture of how these abnormalities alter brain function. Finally, relating imaging findings to genetic variation is an important but largely unexplored avenue that will be fruitful for understanding the molecular changes contributing to CC abnormalities and developing new therapeutics that might improve CC abnormalities in individuals with autism.

Correlation

Domenic V. Cicchetti

Departments of Psychiatry and Biometry, Yale Child Study Center, Yale University, New Haven, CT, USA

Introduction

The important concept of correlation will cover a number of important areas: defining features, types of correlations, a brief historicity of the concept, and multiple ways to look at the correlation coefficient.

Definition

Correlation refers to a statistical procedure that assesses the association between two variables that we will refer to as X and Y . Correlation coefficients, symbolized as r , can vary between -1 , 0 , and $+1$. Positive correlations occur when Y increases as X increases and negative correlations occur when X increases as Y decreases.

When there is no association between the X and Y variable, the size of r tends in the direction of a 0 value. Finally, correlation rests upon the assumption that there is no so-called causative relationship between the X and Y study variables.

Brief Historicity of the Correlation Coefficient r

As noted by Rodgers and Nicewander (1988), the concept of correlation was introduced, in 1885, by Sir Francis Galton, who developed “the theory of bivariate correlation” as well as the related term “regression.” The concept of r , as we know it today, was introduced a decade later by Karl Pearson (1896). Again, from a historical perspective, the Rodgers and Nicewander publication was written in celebration of the 100th Anniversary of Galton’s critical contribution to the development of the correlation coefficient.

It is important to note also the more far-reaching significance of r when one realizes that “Factor analysis, behavioral genetics models, structural equation models (e.g., LISREL), and other related methodologies use the correlation coefficient as the basic unit of data” (Rodgers and Nicewander 1988, p. 61). In fact, as Henrysson (1971) reminds us, three other correlation coefficients can be accurately defined as special instances of Pearson’s r coefficient: Spearman’s rho and the point-biserial correlation for ordinal data and the phi coefficient for nominal-dichotomous data.

An Application of r

Let us assume that X refers to IQ level and Y to Vineland overall adaptive behavior levels. Assume further that the study group is a random representative sample of typically developing 10-year-olds. Based upon many Vineland standardization samples, we know that the correlation will be of the order of about 0–0.20 between IQ and the adaptive behavior composite, and this is statistically significant at the 5% level of statistical significance. What do we make of the correlation of 0.20 between IQ and overall adaptive behavior? Once again, the all-important level of clinical significance needs to be addressed, this time in the form of criteria developed by Cohen (1988), as expanded by Cicchetti (2008):

Range of correlation, clinical significance:

- <0.10 Trivial
- 0.10–0.29 Small
- 0.30–0.49 Medium
- 0.50–0.69 Large
- 0.70–1.00 Very large

By these clinical criteria, the correlation of 0.20 between IQ level and overall adaptive behavior level is considered small. It should be noted that similar results occur for the Vineland Domains, Daily Living Skills, Socialization, and Motor Skills.

As expected on the basis of the content of the items, the correlation between IQ and the

Communication Domain is somewhat higher, in one study reaching an r value of 0.36 (Sparrow et al. 2005). By the same set of clinical criteria, this represents a medium level of clinical significance.

In the next section, I shall discuss a multitude of different ways to understand the meaning and rather far-reaching implications of the coefficient r . Thirteen were described by Rodgers and Nicewander (1988); a 14th was added by Rovine and von Eye (1997); and a very general purpose r related index was developed and introduced by Rosenthal and Rubin in 1982. Each of these will be discussed in turn:

Thirteen ways to interpret r (derived from Rodgers and Nicewander (1988)):

1. r as Pearson (1896) defined it, or as it is typically applied, based upon raw score and average or mean values
2. r as a ratio of standard deviations
3. r as the standardized slope of the regression line
4. r as the geometric average of the two regression slopes
5. r as the proportion of variability accounted for
6. r as the average cross product of standardized variables
7. r in relation to the angle between two standardized regression lines
8. r in relation to the angle between the two variable vectors
9. r as a rescaled variance of the difference between standardized scores
10. r as estimated from the balloon rule: note that the “balloon” is formed by drawing an ellipse around the scatterplot of the individual X and Y values
11. r as a more formal representation of the balloon rule
12. r as related to test statistics from designed experiments
13. r as the ratio of two means
14. r as the proportion of matches between standardized X and Y values
15. r as its mathematical relationship to the d statistic, as given in Cohen (1988, p. 23), by the following formula: $r = d/(d^2 + 4)^{1/2}$

A fundamental biostatistical research question pertains to the extent to which some future researchers in the field of autism spectrum disorders will find some of these imaginative interpretations of the correlation coefficient useful in providing further clinical insights into the vagaries and vicissitudes of ASD disorders.

In the next section, I shall present some novel interpretations of the meaning of the correlation coefficient r , as presented by Rosenthal and Rubin (1982).

The Binomial Effect Size Display (BESD)

A standard way of interpreting the clinical importance of the size of a correlation coefficient, r , is to simply square its value. This informs us about how much of the explained variance in the Y variable can be attributed to the variance in the X variable. The result is expressed as a percentage score that will vary between 0% (a 0 correlation) and 100% (a perfect correlation, of either +1.00 or -1.00). Thus, a correlation of size 0.32 would be viewed as very low or somewhat trivial, since it accounts for 0.32 squared, or only 10% of the explained variance in the Y variable that can be predicted by the X variable. This would leave as unaccounted variance a whopping 90%! And, in fact, this is the reported success rate of psychotherapy, as reported by Randolph and Edmondson (2000).

While the traditional way of interpreting the psychotherapy outcome study seems rather wimpy, indeed, the work of Rosenthal and Rubin (1982) suggests otherwise. Using what they referred to as a binomial effect size display (BESD), the authors cast a given correlation between the X and Y variables into a 2×2 contingency table, and the approach is applicable whether the original data were derived from categorical or continuous scales of measurement.

Applying the BESD to the Success of Psychotherapy Intervention

The reported r of 0.32, representing the success of psychotherapy intervention, is now considered in

the context of a Treatment Group (the one that receives psychotherapy) and a Control Group (the one that does not receive psychotherapy).

The cells in the 2×2 BESD contingency table are expressed as 4%, each starting and ending at 50%. If the r is 0, then the percentages remain unaltered and indicate 0 success for the psychotherapy intervention. This means that 50% of the subjects in the Treatment Group show positive results and 50% do not. This is no different than the results for the Control Group and makes perfect clinical sense in terms of an r of 0.00 between X , reflecting the type of treatment (Therapy or Not) and Y , reflecting the outcome of the intervention (Success or Failure).

Now, in our application, the actual $r = 0.32$. The BESD will inform how much better than a 0.00 r is one of 0.32.

Using the $r = 0.32$ as a measure of Effect Size (e.g., Cohen 1988; Rosnow et al. 2000), the r is divided in 2, with this value of 0.16 both subtracted and added to the 50% value in each of the two groups. This then represents the amount of improvement provided by the treatment intervention. In our example, this results in percentages of (50% - 16% = 34%) and (50% + 16% = 66%). The result is now interpreted to mean that the r between treatment and success rate of 0.32 indicates that psychotherapy intervention has resulted in a 34–64% increase in success rate or 14% over the 50% one would have expected if the therapy had no effect at all. As noted correctly and initially by Rosenthal and Rubin (1982), even though the r of 0.32 only explains 10% of the variance in success rate, when interpreted in a BESD context, the result can hardly be interpreted as of little clinical value. In summarizing this section of the report, I present, in Table 1, the results of comparing the meaning and interpretation of the various values of a correlation coefficient, r .

The table is constructed to show what happens to the values of r squared, the success of a Treatment intervention, and the level of clinical importance of the research result, as the correlation between the X and Y variable increases from 0 to a perfect correlation of 1.00.

Correlation, Table 1 Comparing and contrasting ways to interpret the meaning of the Pearson correlation coefficient, r

Value of r	r squared	BESD % success	Clinical significance of r
<0.10	<0.01	<55	Trivial
0.10	0.01	55	Small
0.20	0.04	60	Small
0.30	0.09	65	Medium
0.40	0.16	70	Medium
0.50	0.25	75	Large
0.60	0.36	80	Large
0.70	0.49	85	Very large
0.80	0.64	90	Very large
0.90	0.81	95	Very large
1.00	1.00	100	Perfect r

While the levels of clinical significance presented here for the correlation coefficient, r , will be applicable in a multitude of clinical research applications, there are situations in which this is not the case. When this occurs, a statistic other than r will be more appropriate. A classic example has been the binary relationship between whether one takes a daily aspirin or does not and whether one has a heart attack or not. The r between the two binary variables is a mere 0.033. Yet, when the odds ratio is, instead, applied to the data, it produces a value of 1.82, meaning that those not on aspirin had almost twice the odds of experiencing a myocardial infarct than those taking aspirin (Kelley and Preacher 2012; Steering Committee of the Physicians’ Health Study Research Group 1988).

Concluding Comments

This report covers the correlation coefficient for determining the degree of linear relationship between a pair of variables designated as X and Y . It did not cover a number of related issues, not because they are not of research importance in a larger sense but, rather, because studies that focus upon curvilinear relationships among ASD-relevant variables are notable for their absence in the field. Another way of stating this phenomenon is that the relationships we typically study in ASD

research are of a linear nature or quality. For similar reasons, this section on correlation has not focused on multiple correlation.

Structure

Anatomical Organization of Language Cortex in Autism

Cortical language areas are primarily centered around the perisylvian cortex, particularly in the left hemisphere. While the left posterior superior temporal gyrus (LSTG, BA 22, Wernicke's area) has been attributed to decoding language, the left inferior lateral prefrontal cortex (LIFG, BA 44/45, Broca's area) has been associated with motor expression of speech. In other words, Broca's area is the language production center, whereas Wernicke's area is the language comprehension center. In addition to these primary centers, there are several other areas involved in processing

language. For instance, the inferior parietal lobule (IPL) has a critical role in processing language because it is located at the junction of the auditory, visual, and somatosensory cortices. The IPL also shares connections with several other areas in the brain that are implicated in language processing. Other regions involved in language processing include the angular and supramarginal gyri (both are part of IPL), the planum temporale (PT), the insula, Heschl's gyrus (HG), and the parietal operculum. Heschl's gyrus is located within the Sylvian fissure, just anterior to the PT; whereas, the PT is located within the Sylvian fissure, posterior to HG and lies on the superior surface of the posterior STG. Many of these regions are anatomically connected through the arcuate fasciculus (AF), an axonal fiber bundle that arches around the ventral part of the frontal lobe and the posterior part of the temporal lobe.

Impairments in language and communication feature are one of the defining characteristics of autism spectrum disorders (ASD). Neuroimaging studies have found deviant functional brain responses as well as altered anatomical organization of the language cortex in people with ASD. One of the main anatomical abnormalities associated with the cortical language areas in ASD pertains to a reversed asymmetry in the normally left hemisphere dominant structures. For instance, studies have found decreased gray matter in Broca's area in people with ASD in comparison to typically developing individuals. Moreover, the right hemisphere homologue of Broca's area has been found to be much larger in 7–11-year-old children with ASD compared to typically developing peers. Such findings are also supported by evidence from neuronal density and neuronal volume in those with ASD. The differences in asymmetry may be due to a difference in the number of neurons present or possibly how densely they are packed together.

Although there are consistent findings of abnormal asymmetry of language association cortex in Broca's area for individuals with ASD, the picture is less clear for the relatively posterior language areas, such as Wernicke's area and the PT. Typical individuals with leftward lateralized language cortex generally also have leftward

lateralization of the PT. However, there is evidence from PT tracings that suggests there is no association between PT size or asymmetry and the lateralization of language cortex. More recent research noted a significant enlargement of the PT in the right hemisphere of individuals with ASD. Other research, however, has contradicted this finding by demonstrating reduced PT volume in the left hemisphere in ASD and no difference in the volume of Heschl's gyrus. There is also evidence that suggests that PT asymmetry may be related to language impairment; it has been found that individuals both with ASD as well as typical controls with language impairments have more leftward PT asymmetry than individuals with no language impairment. Therefore, language impairment may be an important variable in affecting or causing PT asymmetry. It is possible that age may be another factor that influences the organization of this region. Studies show age-related changes in the PT in both typically developing individuals and in individuals with ASD, with both groups showing increased leftward asymmetry in older than younger individuals.

The difference in asymmetry found in structures like the PT and the STG in people with ASD may directly point to problems associated with auditory processing of language. Children with ASD have been found to process nonspeech sounds abnormally early in development which implies that the deficit may stem from faulty organization of language processing areas within the auditory cortex. For instance, decreased gray matter volume of the left STG has been seen in children with ASD relative to participants without ASD. In addition to the alterations found in PT and STG, increased gray matter volume of the auditory cortex in individuals with ASD has been found in the periamygdaloid cortex, the left middle temporal gyrus, and the right inferior temporal gyrus. These anatomical alterations associated with language processing areas may be a key factor affecting language and communication difficulties in ASD. Many studies point to gray matter anomalies as the causal difference in language processing abilities of individuals with ASD. Such abnormalities are mostly due to the volume,

asymmetry, or neuronal organization of a region rather than lesions of a certain region.

Anatomical Connectivity of Cortical Language Areas

As previously mentioned, morphometry and lesion studies have found alterations in the volume and asymmetry of cortical language areas in individuals with ASD. Such impairments can have a significant impact on the organization and integrity of the anatomical connections among these regions. These connections, formed by axonal fiber tracts, provide the mechanism by which information is transferred from one area to the other. The arcuate fasciculus (AF) is a critical white matter fiber tract for language as it primarily connects the anterior and posterior core language areas. While the direct segment of the AF connects Wernicke's area with Broca's area, an indirect pathway connects these areas with the inferior parietal lobule. Specifically, the anterior segment of the indirect pathway connects Broca's area with the inferior parietal lobule and the posterior segment connects the inferior parietal lobule with Wernicke's area. The functioning of the typical language network relies heavily on the direct and indirect projections from the AF connecting these areas. Microstructural differences in the organization and asymmetry of AF found in people with ASD suggests that atypical asymmetry in people with ASD may be affecting language ability. Another fiber tract that is important for language is the uncinate fasciculus (UF), a hook-shaped fiber bundle that connects the anterior temporal lobe with the orbital frontal cortex including the IFG. Abnormalities in the UF fiber organization in individuals with ASD have recently been found in a Diffusion Tensor Imaging (DTI) study with the people with ASD showing shorter length of the left UF fibers as well as increased length, volume, and density of the right UF. These alterations in fiber organization in AF and UF may underlie the functional abnormalities associated with processing language in people with ASD.

It may not be a coincidence that the asymmetry seen in gray matter associated with language processing is also found in white matter in people with ASD. The differences in hemispheric

lateralization in those with ASD need to be discussed in the context of the structural integrity of the major white matter tract – the corpus callosum – that facilitates the communication between the two hemispheres. Reduced size of the midsagittal area of the corpus callosum in people with ASD has been widely reported. Despite this relatively consistent finding, the size of the subregions of the corpus callosum in those with ASD has been found to vary as some researchers found the reduction to be centered in anterior subregions like the rostrum and genu and others in the body of the callosum or in the splenium. In the context of language processing, the genu and the posterior midbody may be critical as the fibers pass through the former and connect the left and right frontal language areas and fibers passing through the latter connect the left and right temporal and parietal language areas. Research findings indicate the involvement of the corpus callosum in understanding humor, prosody, and decoding the nonliteral meaning within context. These complex linguistic functions may require communication between the two hemispheres that is facilitated by the corpus callosum. Therefore, it is possible that the alterations seen in the organization of the corpus callosum may constrain the language abilities of individuals with ASD.

Function

Functional Specialization of Language Cortex in ASD

Functional specialization and integration go hand-in-hand during brain development. Any faulty element in this delicate process can have a significant impact on how different brain regions respond to a given function. Abnormal specialization of language association cortex in people with ASD has been reported by several studies. For instance, individuals with ASD may have a faulty early perception of language due to impaired feature extraction, such as the correct decoding of phonemes or auditory language encoding. This may result in the left hemisphere language areas not receiving the proper input that

would allow for them to develop normally. When this normal input is not processed correctly early in the pathway, the brain does not receive accurate feedback that allows for the normal maturation of language cortex. In other words, deviant cognitive processing of external stimuli in those with ASD may cause a secondary neurobiological assault, which in turn may result in altered specialization of cortical areas. Due to language specialization occupying abnormal regions of the cortex in people with ASD, those areas may not be capable of functionally supporting language processing to the same extent as seen in typically developing individuals. The alterations in functional specialization in cortical language areas may result in different patterns of recruitment of cortical regions, especially between the two hemispheres.

Differential Recruitment of the Hemispheres

Perhaps mirroring the anatomical differences in the asymmetry of language association cortex, people with ASD have been found to recruit more right hemisphere areas in language tasks. In studies involving the processing of spoken language in individuals with ASD, the main findings have consisted of abnormal frontal and temporal activations, as well as reversed laterality in some regions. Functional MRI scans of babies (2–3 years old) during sleep have reported an increase in activation of right hemisphere regions in children with ASD. In addition to the deficits seen in temporal processing of speech in people with ASD, their difficulty in processing spoken language in the presence of noise was demonstrated by examining cortical encoding of speech in children. The left hemisphere is considered to be responsible for processing the temporal aspects of sound, such as encoding the sound properties of speech. Therefore, sound features that activate higher order language processing areas may not be representing the characteristics of the sound that are required in order to engage left hemisphere areas which are important in language processing and for causing language to lateralize to the correct hemisphere. Several other fMRI and PET studies examining auditory processing also found that people with ASD had less temporal

lobe activation and less activation that was lateralized to the left.

Other aspects of auditory processing, such as phonemic and prosodic variations in the context of spoken word, have also been found to be accomplished differently in people with ASD. They have abnormal functional lateralization within the left temporal area when processing phonemes. This is indicative of the fact that when left hemisphere dominance is not established, language impairments are more prominent. Impairments in the processing of prosody (pitch, rhythm, and stress patterns of language), have been reported in low- and in high-functioning people with ASD. Research shows that people with ASD are worse than typically developing controls at understanding the stress differences within words. At the neural level, while individuals with ASD show decreased recruitment of the left superior temporal sulcus in response to vocal sounds, they display typical activation in response to nonvocal sounds. Correct processing of prosodic information has been found to help initiate language acquisition and to help understand the mental states of others. Therefore, difficulty with prosody can have a significant impact in understanding and using language in social situations.

Differential Functional Activation and Functional Connectivity of Core Language Areas

Semantic and discourse processing (auditory or visual) have also resulted in altered brain responses in people with ASD. In tasks of sentence comprehension, Wernicke's area is more activated and Broca's area is less activated in people with ASD; whereas an opposite trend is observed in typical individuals. This pattern of brain response (increased activation in Wernicke's area) may suggest an increased reliance on word meaning and less emphasis on integrating words at the sentence level to arrive at meaning. This differential recruitment of core language areas has also been found at both the sentence level as well as at the word level in those with ASD. Broca's area has been proposed as a vital component of language processing, especially for mediating semantic integration and for the unification of

the components needed for processing language. Weakened integrative capacities have been reported in ASD in tasks that target contextual processing in semantic anomalies. When examining the integration of speaker information, Broca's area is not activated as highly by individuals with ASD as it is by typically developing participants. Yet, individuals with ASD showed increased activation in the right hemisphere homolog to Broca's area while comprehending speaker-incongruent sentences when compared to controls. The pattern of activation that is evident from these studies suggests that the differences in recruitment of language areas as well as a possible compensatory processing may be due to a spillover effect from the left hemisphere.

In addition to the activation of brain areas for accomplishing a task, the functional connectivity (synchronization of brain activation across activated areas) is critical in solving complex cognitive tasks. For instance, there is significant functional connectivity between Broca's and Wernicke's areas when listening to speech in typically developing individuals. Brain responses in complex language tasks in people with ASD have been found to be characterized by weaker connectivity among core regions. Weaker functional connectivity in ASD has been reported in tasks of active and passive sentence comprehension, sentence imagery, and in discourse processing. Such weak connections are usually found between regions that are critical for the task at hand, for example, there is a weaker connection between Broca's area and IPL in sentence imagery, and between Broca's and Wernicke's areas in sentence comprehension. In people with ASD, connections between the parietal and temporal lobes allow for their increased reliance on this area for processing, perhaps as an alternate route, along with reduced connections between Broca's and Wernicke's areas. Therefore, functional connectivity may play an equally important role in language processing as does functional activation.

Compensatory Strategies

Despite widespread reports of altered recruitment of cortical regions for language comprehension, many studies fail to find a pronounced difference in task performance in people with ASD

suggesting the possible use of compensatory strategies. One such mechanism may be an increased reliance on right hemisphere areas. Additional recruitment of right hemisphere brain regions is usually seen in typically developing individuals when task demands are increased and when higher-level language processing is needed. In studies of discourse processing and in detection of communicative intent, it has been found that people with ASD show increased right hemisphere activation in the homologues of core language areas. Such tasks are complex and may require the involvement of a network of coarse semantic processing, coherence monitoring, text integration, spatial imagery, and perspective taking. While any inference may elicit a right hemisphere response in people with ASD, only certain inferences, which are extremely difficult, may elicit that pattern in typical controls. This spillover effect has been demonstrated in other studies involving linguistic stimuli of differential difficulty in typical individuals and in story comprehension. Lesion studies have shown that damage to the left temporal pole causes difficulties in recalling stories whether they are spoken or written. This occurs even when participants have normal sentence comprehension skills and normal working memory. When listening to stories in particular, people with ASD activate the left temporal pole which is involved in recalling linguistic content. They also activate the right temporal pole which is involved in encoding and storing the prosodic and pragmatic aspects of the story. This finding was also demonstrated when the subjects were required to read the stories. These areas were recruited when the task demand increased, in contrast to simple lexical and semantic processing of single words. Therefore, these studies suggest that individuals with ASD may show bilateral activation regardless of difficulty.

Increased recruitment of relatively more posterior cortical language areas is another alternate neural route seen in those with ASD. In sentence comprehension studies involving high and low visual imagery, greater recruitment of parietal regions was found in participants with ASD irrespective of the presence of high or low imagery content. Similar results were also found with increased occipital activation in individuals

with ASD during semantic decision making tasks with a decrease in activation of the frontal verbal areas. These findings are also in line with Temple Grandin's view of "thinking in pictures" by recruiting visual and visuospatial regions to assist complex cognitive or linguistic processing. Research has also found weaker synchronization between language (left inferior frontal) and spatial (superior parietal) areas in people with ASD as compared to typically developed controls which further suggests focal or modular processing as opposed to integrative processing that is seen in control participants. Such findings were also supported by computational modeling techniques suggesting low level perception in individuals with ASD is superior and accessed easily compared to higher-level "top-down" cognitive processing.

Conclusion

This entry describes the anatomical and functional organization of cortical language areas and the abnormalities associated with them in people with ASD. In addition, it also deals with the ways in which cortical language areas participate and communicate with one another in ASD. The functional abnormalities seen in key language areas (Broca's and Wernicke's areas) as well as the differences in the organization of language association cortex in ASD may produce notable difficulties in language and communication. Explaining any cognitive function in ASD is difficult, as it may reflect the complexity of the disorder itself. The organization of language association cortex during brain development and the potential problems associated with it may affect subsequent functional and anatomical specialization. It is not clear whether the abnormal organization is neurobiological or is in turn the result of a secondary assault on the brain by early deviant behaviors in children with ASD, or both. Nevertheless, it should be noted that the brain of an individual with ASD, perhaps like the typical brain, adapts in certain ways to compensate for weaker connections and altered organization. Such adaptations, reflected in neuroimaging studies of language, may involve increased right

hemisphere recruitment, and an increased recruitment of relatively posterior language areas as well as visuospatial areas. Such atypical use of brain resources for solving cognitive and linguistic tasks may be a cause or a consequence of the altered organization and/or the difference in connectivity seen in individuals with ASD. Another factor that may complicate this topic is the heterogeneity seen in the ASD population in general and in their language abilities in particular. Learning about the organization, recruitment, and connectivity of cortical language areas in ASD should facilitate researchers as well as clinicians in making informed decisions and plans for language-based intervention in people with ASD.

Pathophysiology

The path of physiology of ASD is increasingly complex, perhaps reflecting the intriguing nature of the syndrome itself, with abnormalities found in several brain structures and in neurochemicals on a cellular level in cortical and subcortical structures. Significant cerebral hypo-perfusion (decrease of blood flow within the brain) has been widely reported in individuals with ASD especially in bilateral superior temporal cortices. This decrease in blood flow has been found to be more prevalent as the age of the child increases. A decrease in blood flow to the temporal lobes has been proven to cause impairments in communication, decreased language development, and auditory processing problems. The decreased blood flow has been hypothesized to be a result of vessels within the brain constricting rather than dilating which can lead to hypoxia and result in cell death. The constriction of blood vessels has been attributed to inflammation in the cortex of individuals with ASD. Abnormalities have also been reported in neuronal migration in postmortem cases of people with ASD along with abnormal minicolumn pathology, disrupted neuronal development, and glial cell abnormalities. Many of these abnormalities can have a significant impact on the organization of the brain in ASD.

Abnormalities in neurochemistry can also lead to problems in normal development of the brain. For instance, neurotransmitters like serotonin

regulate neurogenesis, synaptogenesis, neuronal removal, and differentiation. Normal high serotonin synthesis and synaptogenesis that takes place in early childhood is not seen in children with ASD. Although high levels of blood serotonin are found in children with ASD, it seems that they have below normal levels within their brains. It has been proposed that certain binding proteins (Mbd1) that are components of the “methylation-mediated epigenetic gene regulation system” could be an underlying factor in the dysfunctional serotonergic system seen in ASD. Studies show that mice who were missing this gene exhibited autistic like characteristics. Abnormalities in other neurotransmitters, such as the *N*-Acetyl Aspartate (NAA) and in glutamate were also reported in people with ASD. Together, these pathophysiological factors could play a significant role in causing disruption in the typical functioning of the brain in individuals with ASD.

Definition

Cortisol is a stress hormone secreted into the blood by the adrenal cortex of mammals. Its short-term effects of increasing metabolism, increasing blood sugar, and decreasing inflammation help the organism respond to stress and maintain homeostasis. Long-term elevations in cortisol can have a number of detrimental effects on the body and, perhaps, on the brain. Cortisol secretion by the adrenal is controlled by adrenocorticotrophic hormone (ACTH) secreted by the pituitary, with ACTH secretion in turn controlled by corticotrophin-releasing hormone (CRH) secreted by the hypothalamus. Cortisol exerts its peripheral and central effects by binding to the glucocorticoid receptor (GCR) found on most cells. Cortisol has been measured in the plasma, serum and urine of individuals with autism in order to assess their exposure to and response to stress, and their level of arousal. When taken together, prior studies appear to indicate that cortisol production is similar in individuals with autism compared to controls. However, there is some evidence that the normal diurnal rhythm of cortisol secretion (highest in the morning, lowest at night) might be altered in some individuals with autism.

Counterfeit Deviance

Rachel Loftin¹, Alexander Westphal² and Laurie A. Sperry³

¹AARTS Center, Rush University Medical Center, Chicago, IL, USA

²Division of Law and Psychiatry, Yale Child Study Center, Yale School of Medicine, New Haven, CT, USA

³Department of Psychiatry, School of Medicine, Yale University, New Haven, CT, USA

Definition

The term “counterfeit deviance” is used to describe inappropriate behavior rooted in factors

other than true deviance. It is most often used in the context of inappropriate sexual behavior, in which the observed behavior looks paraphilic but, upon closer examination, was the result of other factors. Counterfeit deviance has been the focus of more discussion in the intellectual disability literature than in the autism-specific literature. There are clinical examples of its occurrence even among people with ASD who have adequate intellectual ability.

Traits associated with autism spectrum disorder (ASD) – including but not limited to difficulty taking another person’s perspective, social naiveté, preoccupation with particular areas of interest, differences in sensory perception – may make this population prone to situations that cause counterfeit deviance, particularly when the behavior of the person with ASD is assessed by someone unfamiliar with these traits. While one should always consider whether an observed behavior is merely counterfeit deviance, it is possible for a person with ASD to display a real deviant sexual interest or drive.

One clear example of counterfeit deviance is an 18-year-old young man with ASD and intellectual disability who was arrested for indecent exposure. He was taught at school that masturbation was something that he should do only at home. One day at home he masturbated in his backyard. The boy was spotted by a neighbor who called the police. When later asked why he masturbated outside, the boy said he thought it was allowed because he was “at home.” He was not aware that it would be problematic for anyone to see him. Counterfeit deviance occurred when he was viewed masturbating outside and assumed to be engaging in this behavior as a public display (i.e., exhibitionism).

[Adult follow-up studies](#); [Adulthood, transition to](#); [Factors affecting outcome](#); [Natural history](#); [Outcome](#); [Outcome studies](#)

Definition

Autism is a lifelong disorder characterized by core problems in social communication and the presence of stereotyped and repetitive behaviors. However, the manifestation of these problems can change over time. In many cases, the severity of autistic symptoms decreases with age; in others, difficulties may become more evident as individuals grow older. In adolescence and adulthood, many individuals also develop additional mental health problems, particularly related to anxiety and depression.

The course of development is highly variable and often very difficult to predict. The most positive outcomes tend to be for individuals who develop useful speech in childhood and have an IQ in the normal range (i.e., 70+). Nevertheless, even among this group, some individuals remain highly dependent as adults. A good outcome also depends on the adequacy of intervention and support available during child- and adulthood.

Course of Social Avoidance in Fragile X Syndrome, The

Abigail L. Hogan¹, Hayley Crawford² and Jane Roberts¹

¹Department of Psychology, University of South Carolina, Columbia, SC, USA

²Coventry University, Coventry, UK

Definition

Social avoidance includes failure to initiate interactions, reduced time spent interacting with others, and social interaction restricted to a subset of preferred individuals. Elevated social avoidance is often associated with negative outcomes including reduced relationship quality and educational/vocational difficulties. High levels of social avoidance are commonly observed in individuals with autism spectrum disorder (ASD), attention-deficit/hyperactivity disorder (ADHD), and anxiety.

Fragile X syndrome (FXS) is a monogenic disorder associated with ASD. In males with FXS, social avoidance emerges in infancy, increases through early childhood, and stabilizes at a high level across adolescence and adulthood. Increased social avoidance across infancy and preschool predicts more severe ASD symptoms but reduced ADHD and anxiety symptoms in children with FXS.

Autism is a lifelong disorder characterized by core problems in social communication and the presence of stereotyped and repetitive behaviors. However, the manifestation of these problems can change over time. In many cases, the severity of autistic symptoms decreases with age; in others, difficulties may become more evident as individuals grow older. In adolescence and adulthood, many individuals also develop additional mental health problems, particularly related to anxiety and depression.

The course of development is highly variable and often very difficult to predict. The most positive outcomes tend to be for individuals

who develop useful speech in childhood and have an IQ in the normal range (i.e., 70+). Nevertheless, even among this group, some individuals remain highly dependent as adults. A good outcome also depends on the adequacy of intervention and support available during child- and adulthood.

Court Decision (ASD Related)

John W. Thomas
Independent Educational Consultant, Durham, NC, USA
Quinnipiac University School of Law, Hamden, CT, USA

Definition

Court decisions involving ASD occur in a number of legal contexts. Perhaps the most common decisions address the issue of insurance coverage for the treatment of ASD. In the private insurance context, the dispute often centers on

coverage of behavioral therapies (Barner 2009). Insurers contend that these treatments are experimental or are educational services rather than health services. Court decisions turn on both the specific language of the policy at issue and the mandates of state laws (Barner 2009). Court decisions often also address the extent to which early intervention, custodial services, and other treatment modalities are covered by specific insurance policies.

Public health insurance also presents issues of ASD treatment coverage. Decisions regarding eligibility for coverage in Medicaid and other governmental programs often depend on whether a given intervention is classified as a mental health treatment, physical health treatment, or a neurodevelopmental therapy (Treatment 2009).

The educational setting provides another major context for court decisions regarding ASD. Litigation in this area often concerns the mandates of the federal Individuals with Disabilities Education Act (IDEA). IDEA's goal is "to ensure that all children with disabilities have available to them a free appropriate public education that emphasizes special education." The statute also mandates the provision of "related services designed to meet their unique needs and prepare them for further education, employment, and independent living." Services must be articulated in an Individualized Education Program (IEP). Litigation and resulting judicial decisions depend on a court's conclusion whether the process provided the student and the IEP itself in accord with the United States Supreme Court's decision in *Board of Education v. Rowley*. There, the Court held that the student must be provided with a fair process and that the IEP must be "reasonably calculated to enable the child to receive educational benefits."

ASD also plays a role in civil litigation between private parties, including the tort litigation contending that the MMR vaccine causes ASD (Thomas 2010). These cases, now totaling nearly 6,000, are being prosecuted under the National Vaccine Injury Compensation Program (Thomas). Individuals claiming an injury from a

covered vaccine must file a claim for "no-fault" compensation with the US Court of Federal Claims. The claims are resolved not by juries but by special masters. To date, the special masters have ruled against the plaintiffs on all six test cases, and all of those decisions appealed to higher courts have been affirmed. The Court of Claims has awarded compensation where the complaining child suffered from a preexisting mitochondrial enzyme deficit (Offit 2008).

On February 22, 2011, the United States Supreme Court ruled that the National Childhood Vaccine Injury Act (NCVIA) prohibits complainants from filing lawsuits against vaccine manufacturers. Rather, all such claims must be filed with the special Federal Court of Claims established under the National Vaccine Injury Compensation Program (Bruesewitz).

COVID-19 and Its Impact on Individuals with Autism Spectrum Disorder

Ismail El Hailouch

School of Public Health, Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Description of COVID-19

Coronaviruses (CoVs) are a group of diverse, enveloped, positive-sense, sing-stranded RNA viruses belonging to the subfamily Orthocoronavirinae in the family Coronaviridae, Order Nidovirales (Li et al. 2020). CoVs are known to cause disease in humans and animals, and can affect nervous, respiratory, hepatic, and enteric systems. In December 2019, patients in Wuhan, China, presented with pneumonia of unknown cause. It was determined after genome sequencing that the pneumonia – termed coronavirus disease 2019 (COVID-19) – was caused by a novel CoV, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) (Xu et al. 2020). Symptoms of the disease include mild to moderate respiratory illness, fever, and loss of smell.

Current Knowledge

State of Emergency

On January 20, 2020, the WHO declared COVID-19 a public health emergency, and eventually declared it a pandemic on March 11, 2020 (Dhama et al. 2020). This marked the first pandemic since the 2009 outbreak of H1N1. Initially, the majority of the public health burden associated with COVID-19 was confined mostly to China. However, the disease quickly spread to Europe and the United States of America (USA). The European countries that were affected most severely are Italy and Spain, but the USA has the largest number of confirmed cases and deaths due to COVID-19. The COVID-19 pandemic has resulted in stringent lockdown measures being

implemented worldwide, and has caused severe economic losses due to sudden disruptions in production and trade. Unfortunately, most of the governmental measures implemented worldwide have been reactive rather than proactive, and were not implemented early enough to minimize societal disruptions.

COVID-19 Effects on Mental Health

Many governments worldwide have adopted similar measures to combat COVID-19. These measures typically involve some level of lockdown, wearing masks, quarantining if necessary, and limiting social gatherings. While these measures have proven effective at slowing the spread of COVID-19, they have had a particularly negative impact on regional and global economies (Adhikari et al. 2019). Additionally, these stringent public health measures have caused adverse psychological impacts on the general population.

Studies show that negative psychological effects of the COVID-19 pandemic result from the unpredictability, uncertainty, misinformation, and social isolation surrounding the situation (Zandifar and Badrfam 2020). Vulnerable populations are especially at risk of developing adverse psychological symptoms due to the increased level of stress and panic caused by the possibility of developing complications if affected by COVID-19. The increased level of fear and panic among the general population can be highlighted by certain behaviors such as stockpiling household supplies and behaving violently toward those not following public health guidelines (Shigemura et al. 2020).

Many have hypothesized that the COVID-19 pandemic may lead to a global mental health crisis which would require large-scale psychological interventions and lasting reform of mental health care (Dong and Bouey 2020). Western countries have already begun to address mental health treatment in more recent protocols to combat COVID-19. However, countries such as China have yet to implement psychological interventions to reduce the mental health burden on not only affected individuals, but the general population.

COVID-19 Disruptions in the ASD Community

Those with autism spectrum disorder (ASD) – whether they be high-functioning individuals with Asperger’s syndrome or low-functioning individuals with severely debilitating autism – generally display a preference for specific daily routines (Fuld 2018). Any deviation from their daily routine may result in moderate to severe feelings of anxiety and stress. While governments worldwide have rightly implemented stringent lockdown measures, people with ASD have largely been forgotten. Lockdown, virtual learning, and wearing masks outdoors have resulted in severe disruptions in the lives of those with ASD. Government officials have rarely addressed this significant, vulnerable population in public health protocols. Some countries worldwide, such as the United Kingdom (UK), have relaxed public health protocols for those with ASD (Patel et al. 2020). However, these accommodations only came following legal challenges with the ASD community.

The COVID-19 pandemic poses a significant and continuous source of distress for those with ASD. The uncertainty surrounding the pandemic, as well as the continuous stream of new information regarding COVID-19, may worsen the mental health of those with ASD, even if they do not have an existing mental health comorbidity. One of the most significant sources of psychological stress for those with ASD is the sudden change in routine following the implementation of public health measures (Patel et al. 2020). Caregivers were often unable to provide warning of the impending changes in lifestyle, which likely exacerbated the feelings of psychological distress in those with ASD.

Individuals with ASD often meet with healthcare providers on a regular basis for check-ins and therapy. Additionally, many attend special education schools where they are engaged in various therapeutic educational programming. Due to COVID-19, there are many concerns as to whether such individuals can continue receiving these important services and treatment. A significant portion of schools in the USA and abroad have adjusted their curricula to include some form of virtual learning. This is also the

case for special education schools serving students with ASD. Adjusting to an at-home virtual learning environment provides significant challenges for individuals with ASD who already struggle with maintaining attention and completing tasks in-person (Patel et al. 2020). Without the in-person instruction of specialized educators, the parents must play a larger role in the educational process, posing additional strains on the family of individuals with ASD. Another important factor to consider is physical activity, as the social distancing parameters have caused many to live a sedentary lifestyle (Erkan and Oğuz Kaan 2020). Individuals with ASD often require some form of physical activity throughout the day, and governments have often loosened the outdoor public health protocols for those with ASD due to these requirements. Various physical activities that can be done at home have been outlined by researchers and highlight the importance of family participation (Erkan and Oğuz Kaan 2020).

Advice to Help Individuals with ASD to Cope with the COVID-19 Pandemic

Several studies and reviews have been published on methods to help individuals with ASD cope with the disruption the COVID-19 pandemic has caused. One way to assist those with ASD in coping with the disruptions is to structure their day around various activities using a blackboard or some sort of chart (Narzisi 2020). The pandemic will require families with children who have ASD to find new activities for play, and to schedule these activities at specific times throughout the day. Lego therapy and various video/computer games have also been possible suggestions; however, it is important for parents to find out what works best for their own children (Narzisi 2020). Ordering these activities into a daily schedule will help to minimize any resistance or distress surrounding the changes. Another important aspect to consider is how the current pandemic disrupts education for individuals with ASD. Since many academies and schools have now moved to an online platform, students with ASD will need to make quite an adjustment. One case study of five families with individuals who have ASD in the Philippines reported significant

struggles with adjusting to online schooling (Cahapay 2020). Parents reported the importance of communicating to their children the realities of the current pandemic and its impact on daily life (Cahapay 2020). One parent accomplished this by driving their child around the city so that they could see how businesses were closed down, and also tried to teach their child new social behaviors such as wearing a mask (Cahapay 2020). It is important to communicate to individuals with ASD the realities of this pandemic, and furthermore work with families to teach these individuals new social skills that will help them cope with the extended period of time spent at home.

Future Directions

The COVID-19 pandemic has caused significant worldwide disruptions in nearly every facet of daily life. One population that has been forgotten in the midst of new government regulations and public health protocols is the ASD community. Individuals with ASD typically require a specific daily schedule, any deviation from which may result in significant anxiety and distress. Additionally, individuals with ASD are typically involved in some sort of therapy, social work, or special education. Many of these social services are being moved online, which may pose a significant challenge for individuals with ASD. It is imperative that government officials keep the ASD community in mind when deciding on new public health protocols, and that teachers and parents continue to work together to minimize the disruptions caused by this pandemic on the ASD community.

Creak, Mildred

Adam Feinstein
Autism Cymru and Looking Up, London, UK

Major Appointments (Institution, Location, Dates)

- Mildred Creak worked as assistant physician at The Retreat, a mental hospital run by Quakers in York, UK, 1924–1928.
- Took up a post at the Maudsley Psychiatric Hospital, London, 1929.
- Appointed physician in psychological medicine at the Hospital for Sick Children, Great Ormond Street, London, 1946–1963.

Landmark Clinical, Scientific, and Professional Contributions

In the early 1960s, Mildred Creak chaired the working party which established the landmark nine-point criteria for the diagnosis of autism, published in 1961. This work was based on a series of 100 children she had collected herself. Creak suggested that autism, far from being caused by parental inadequacies, was primarily due to genetic – or, as she put it, “constitutional” – factors.

Short Biography

Born in Manchester, UK, in 1898, Mildred Creak was an extraordinary figure in the history of child psychiatry. She qualified as a doctor at University College Hospital in London at the end of the First World War. It was at the Children’s Department of London’s Maudsley Psychiatric Hospital, from 1929, that Creak helped to lay the clinical and academic foundations for what is now one of Britain’s leading centers for the study of child psychiatric disorders. During the Second World War, she joined the Women’s Army Corps as a doctor, serving part of her time in India. From 1946 – when she joined the Hospital for Sick Children in London’s Great Ormond Street – until her retirement in 1963, she played a leading role in establishing the practice of child psychiatry in a pediatric setting. After her retirement, Creak lectured in Perth, Western Australia, and had a unit for autistic children named after her there. She died in the UK in 1993 at the age of 95.

Criminality, Interactions with Law Enforcement, and Potential Correlates of Juvenile Justice Involvement Among Youth with Autism

Alexandra M. Slaughter¹, Sascha Hein², Sarah S. Mire¹ and Elena L. Grigorenko^{1,3}

¹University of Houston, Houston, TX, USA

²Freie Universität Berlin, Berlin, Germany

³Yale Child Study Center, Psychology, and Epidemiology and Public Health, Yale University, New Haven, CT, USA

Objectives

Understanding criminal behavior in juvenile justice-involved youth with autism spectrum disorders (ASD), potential factors associated with involvement in the juvenile justice system (JJS), and experiences of interacting with law enforcement.

ASD and Crime in the Media

In the past decade, the mass media has often inaccurately linked ASD with criminal behavior. For example, perpetrators, including Lauri Love and Gary McKinnon, who hacked into US computer systems, and Adam Lanza, the 2012 Sandy Hook School shooter, were reportedly diagnosed with mild forms of ASD (Holden and Shirbon 2018; Kushner 2011; McCoy 2014). Furthermore, media claimed that Christopher Harper-Mercer, who was the perpetrator in the Oregon community college shooting, and Dylann Roof, the perpetrator in the 2017 Charleston church shooting, also had ASD (Calabresse et al. 2015; Tripp 2017). Even more recently, the media has suggested that Nikolas Cruz, the individual who opened fire at a school in Parkland, Florida, was diagnosed with ASD (Dearen et al. 2018). The mass media typically links ASD to criminality with captivating headlines such as *FLORIDA SCHOOL SHOOTING: Nikolas Cruz was*

Creativity

► [Imagination](#)

diagnosed with autism, ADHD; Students rage against politicians, NRA in anti-gun rally (Dearen et al. 2018) which not only stigmatizes mental health in general but specifically links ASD to criminal behavior, which leads to negative reactions from the public and stigmatizations of the ASD community (Brewer et al. 2017). In fact, ASD advocates have begun to release statements cautioning against connecting ASD to school shootings (Diament 2018).

Moreover, the way in which the mass media links ASD to criminal behavior is problematic methodologically because the media focuses on high-profile, extreme cases which occur rarely within the general population. Furthermore, extensive reviews of the literature have not revealed a direct link between ASD and criminal behavior, including violent criminal activity (Bjorkly 2009; Lerner et al. 2012). Finally, media reports can be misleading because these report do not provide evidence of a formal ASD diagnosis of the perpetrator (Brewer et al. 2017; Maras et al. 2015). Nevertheless, the attention that the ASD community has received in the mass media has led many researchers to turn their attention to understanding criminal behavior among persons, including youth, with ASD.

Youth with ASD in the JJS

Prevalence Rates

ASD prevalence in the general population is 1.7% (Baio et al. 2018) but reports of prevalence rates of JJS involvement among youth with ASD vary widely within the United States (US). The lowest rate of first juvenile court involvement among youth with ASD (i.e., first contact with the JJS) was estimated at 0.02% (Kincaid and Sullivan 2019), which is consistent with another study that revealed the rates of youth with ASD in the JJS in Connecticut between 2006 and 2012 to be 0.04% (Slaughter et al. 2019). However, other studies have reported higher rates of JJS involvement. For example, one study recorded the rate of arrest among youth with ASD to be 4.7% (Rava et al. 2017), and another showed the percentage of youth with ASD who were charged with a crime

to be 5% (Cheely et al. 2012). Among studies conducted outside of the United States, inconsistencies in prevalence rates are also present. Specifically, research in Japan reported ASD prevalence rates ranged from 1.3% to 6.7% across all, but traffic violations and car accidents, charges in three family courts (Kumagami and Matsuura 2009). However, when a specialty family court for sex-related crimes or arson was considered, the prevalence rate was 18.6%. Inconsistencies in these estimates may be related to methodological differences (e.g., samples, statistical approaches), yet it is clear that youth with ASD do come into contact with the JJS.

Types of Crimes

The types of crimes committed by youth with ASD vary, with some studies showing a higher likelihood for these youth of committing crimes against persons compared to youth who did not have a disability (Cheely et al. 2012; Kincaid and Sullivan 2019). Specifically, law enforcers frequently respond to calls related to verbal and physical aggression directed at others, such as family members (Tint et al. 2017). However, other research suggests that youth with ASD are no more likely to commit crimes against person than youth without special educational needs (Slaughter et al. 2019). Special attention has also been paid to sex-related offenses, as one study presented higher rates of sex-related crimes among youth with ASD compared to the general population referred to family courts in Japan (Kumagami and Matsuura 2009). However, when researchers explored sexual offending among individuals with ASD as a follow-up to their original report, there was inconclusive support for the assumption that individuals with ASD commit sex-related offenses (Allely and Creaby-Attwood 2016). With these equivocal findings, it remains unclear as to whether youth with ASD are in fact more likely to commit sex-related offenses.

Studies of property offenses also generated mixed results. Research shows that youth with ASD are less likely to commit property crimes when compared to youth without a disability (Cheely et al. 2012; Slaughter et al. 2019). This may suggest youth with ASD are less likely to be

involved with crimes requiring premeditation when compared to their nondisabled peers. However, this assumption is brought into question with more recent research suggesting that youth with ASD were more likely to commit property crimes compared to youth without disabilities (Kincaid and Sullivan 2019). It is possible that property crimes are committed by youth with ASD who are behaviorally or emotionally dysregulated, as the likelihood of property damage does tend to increase under such circumstances (Hodgetts et al. 2013). In these instances, youth with ASD likely would not have premeditated an offense but could have been arrested for property destruction nonetheless. However, more research is needed to determine intentionality in committing such crimes.

Finally, with regard to recidivism, youth with ASD are not more likely than youth without special educational needs to reoffend (Slaughter et al. 2019), although studies examining recidivism in youth with ASD are scarce. In fact, to our knowledge there have been no other studies that have looked at recidivism rates among youth with ASD. This is surprising since recidivism is a key post-release outcome considered in criminal justice research, and ASD-related work is needed in this area.

A Comparison with Adult Offenders with ASD

Given the shortage in research examining recidivism as well as longitudinal studies of criminal behavior, research on adults with ASD may shed some light as to whether criminal behavior patterns remain consistent over time. A recent literature review examining studies using both criminal records and self-report data revealed that the prevalence of offending behavior among adults with ASD varied across studies ranging from 8% to 26% (Rutten et al. 2017). One study found that the most common convictions (81%) among adults with ASD were for property offenses (Hippler et al. 2010), though other researchers have concluded property crimes were less prevalent among adults with ASD (Rutten et al. 2017). It also appears that adults with ASD may be less likely to commit traffic offenses, and they report taking illicit drugs at lower rates than adults

without ASD (Mouridsen et al. 2008; Woodbury-Smith et al. 2006). With regard to violent crimes or crimes against persons, available research suggests that these crimes are rare in populations of adults with ASD (Björkly 2009; Hippler et al. 2010). However, when these crimes do occur, their common triggers include sensory hypersensitivity, tactile hypersensitivity, and misinterpretation (Björkly 2009). Therefore, it may be informative for future research to attempt to understand offending behavior among those with ASD, especially with regard to crimes against persons, in the context of the disorder.

Taken together, prevalence rates for involvement with the justice system may slightly increase in adulthood when compared to adolescence. There also continues to be some debate as to whether individuals with ASD commit property crimes at higher rates than those without ASD. Furthermore, crimes against persons continue to be prevalent in adulthood, although violent crimes are rare. However, longitudinal research is needed in order to better explore these patterns.

Associated Factors of JJS Involvement

School Discipline

There are several factors that are associated with JJS involvement among youth with ASD. School discipline is one factor that is important to consider as recent research has discovered that school discipline and JJS involvement often co-occur among youth with ASD (Slaughter et al. 2019; Turcotte et al. 2018). Based on teacher reports, some research shows that youth with ASD are 2.5 times more likely to be suspended when compared to youth without disabilities (Ambler et al. 2015). However, other studies suggest they may be less likely to receive such disciplinary actions compared to students who do not have a disability and students with other disabilities, such as emotional disturbance and learning disabilities (Miller and Meyers 2015; Slaughter et al. 2019). Nevertheless, about half of youth with ASD who have come into contact with the JJS have received at least one out-of-school suspension (Slaughter et al. 2019). Additionally, youth with ASD who

have come into contact with the police are more than four times as likely to also have school discipline infractions (Turcotte et al. 2018). Therefore, youth with ASD who are excluded from the supportive environment of the school system through suspensions and expulsions may be at higher risk of coming into contact with the JJS.

Externalizing Behaviors

Additionally, fighting at school that results in a disciplinary referral is associated with reoffending and may serve as a warning sign that youth with ASD are at risk for future JJS involvement (Slaughter et al. 2019). This is supported by other research showing that externalizing behaviors in youth with ASD such as aggression is associated with being stopped, questioned, and arrested by law enforcers (Rava et al. 2017; Tint et al. 2017). Finally, compared to youth whom do not have a disability, youth with ASD are also more likely to be charged for school-based incidents such as disturbing the school, carrying a weapon, assault and battery, or threatening a school employee (Cheely et al. 2012). For these reasons, both externalizing behavior and school discipline may increase the odds of having interactions with law enforcement among youth with ASD.

ASD and Law Enforcement

Interaction with Law Enforcers

Law enforcers may encounter youth with ASD in a variety of situations. Many youth with ASD (i.e., about 49%) elope from the home, and therefore law enforcement may be called when the youth with ASD is lost (Anderson et al. 2012). Officers may also be called when caregivers or teachers cannot manage behaviors like aggression, tantrums, and self-injury (Jang et al. 2011; Matson and Nebel-Schwalm 2007; Tint et al. 2017). Aggressive behaviors are often a primary presenting concern for contacting law enforcers. Finally, youth with ASD may encounter law enforcement in more communal spaces.

Interactions with law enforcement may be extremely difficult for youth with ASD.

Specifically, core characteristics of ASD such as difficulties with social interactions, atypical responses to sensory stimuli, and exhibiting restrictive interests and repetitive behaviors will affect how persons with the diagnosis interact with law enforcers. Law enforcers who are not aware that the youth has been diagnosed with ASD may misinterpret certain behaviors associated with the diagnosis (e.g., not responding to verbal commands, lack of eye contact, repetitive behaviors) as threatening, suspicious, non-compliant, or signaling that the youth is under the influence of drugs or alcohol when these behaviors are merely manifestations of the diagnosis (Teagardin et al. 2012). Additional challenges are present when the youth with ASD is nonverbal and cannot communicate to the law enforcers that they are diagnosed with ASD. Moreover, ASD is often considered a hidden disability, as there are not outward indications of the diagnosis. When law enforcers are not trained to recognize certain characteristics of ASD and respond appropriately, they may unintentionally exacerbate the situation, which may result in trauma, injury, or even fatality (Copenhaver and Tewksbury 2019; Teagardin et al. 2012).

Training Programs for Law Enforcers

There is a growing demand for high-quality training services for law enforcers. For example, one study conducted in England and Wales revealed that only about one-third of police officers reported having received ASD-specific training; and refresher courses are rare (Crane et al. 2016). The number of officers who receive ASD-specific training in the United States is less clear. In general, police officers in England and Wales find ASD-specific trainings to be helpful. However, some are dissatisfied with the training because they felt trainings did not focus on ASD in the context of the justice system, were oversimplified, and lacked practical application as well as relevance to their policing role (Crane et al. 2016). Police officers who have not received police training overwhelmingly report that training would be useful. Work in this area has revealed that police officers would like to receive more information on enhancing communication, minimizing distress,

and specific training for interaction with someone with ASD as it relates to their specific policing role (Crane et al. 2016). This research highlights the need for high-quality training programs that focus on both education and practical utility.

Future Directions

A brief review of the current literature regarding JJS involvement among youth with ASD reveals that much additional work is needed to address both gaps and inconsistencies. This is apparent with regard to the aforementioned equivocal findings such as inconsistencies with regard to prevalence rates, types of crimes, and satisfaction of interactions with law enforcers. Additionally, several limitations exist within the current literature. For one, many studies have been cross-sectional in nature, which highlights the need to study criminal behavior in this population over time. In addition, how ASD was diagnosed (e.g., educational classification, psychological diagnoses) in participants varies across studies, which makes it difficult to draw reliable conclusions. Moreover, few research studies focus on mental health comorbidities and other environmental factors that may increase the risk for JJS involvement (e.g., family factors). This is especially surprising given that many youth with ASD have comorbid medical and psychological diagnoses. There has also been a lack of self-report data collected within this population. Given the limitations of official crime data, which is subject to police and the court's discretion, self-report data (e.g., surveys, qualitative interviews) may, in some cases, provide critical and useful information. Therefore, there are many opportunities for researchers to contribute to the current literature base.

Furthermore, there is a need for more research in the areas of criminal behavior (i.e., types of crime and recidivism), experiences of interactions with law enforcement and the JJS more broadly, as well as factors that may lead to involvement in the JJS (e.g., school discipline, mental health comorbidities, specific ASD traits that increase risk of involvement in the JJS, and social factors). There appears to be a connection between school

discipline and contact with not only law enforcers but also the JJS more broadly. Specifically, more research is needed examining fighting behavior in school. Additional research should also be conducted with youth who have ASD, particularly among those who have been suspended or expelled from the school system. A high number of youth with ASD who have come into contact with the JJS have been suspended from school.

Recidivism rates are important to examine because youth, in general, who have come into contact with the JJS are at an increased risk of coming into contact with the JJS in the future. In theory, youth with ASD are also subject to the increase in risk of coming into contact with the JJS after their first offense. Reasons for how and why youth with ASD recidivate would also be important to explore.

Additionally, many youth in the general population who come into contact with the JJS have mental health comorbidities as well as other environmental factors that increase their risk of involvement with the JJS. However, surprisingly, the research to date has not studied these factors in relation to JJS involvement in youth with ASD. This is especially surprising given medical and psychological comorbidities are very common among youth with ASD (Lai et al. 2013).

Researchers can also use self-report data to understand experiences of police interactions and JJS involvement from youth with ASD. In trying to understand experiences of the JJS, it is important for researchers to study the school environment (e.g., school discipline, arrests on campus, special education services), the crime itself (e.g., triggers), and the experience of interacting with police officers as well as detention staff and juvenile probation officers (e.g., what could have gone better or worse). With regard to rehabilitation, it is also important to examine intent, competency, and remorse.

It also is important to continue to interview law enforcers in order to determine what training they have received and where this training falls short. Current research suggests that specific training topics should include characteristics of the disorder to be aware of as well as effective ways to identify an ASD diagnosis to law

enforcement. Special attention should be paid to how these training programs can incorporate practical skills. Practical skills can be developed via both role-plays and interacting with the ASD community. Moreover, there is a need to develop training programs for youth with ASD and their families so that they are better prepared when they encounter first responders, including law enforcers. Specific topics should include information on how to interact with law enforcers, as well as effective ways to identify an ASD diagnosis to law enforcement.

At a broader level, it appears that aggression is a primary concern for contacting first responders at school, home, and in the community. This highlights the need to develop community-based family support (Tint et al. 2017), as well as support for school personnel so that these behaviors do not escalate to the point that law enforcers must be contacted. It would also be helpful for advocacy groups to create on-hand resources that can be used by first responders in order to become more familiar with ASD in general. To date, there are some online and print resources for first responders and youth with ASD and their families. However, these resources are typically found across many different websites, and it can be difficult to find an aggregated guide of resources. Information in Table 1 provides an overview of currently available resources in this vein. Suggestions below the table include key points from these resource pages, as well as the clinical experiences of the authors. It is important to note that Dennis Debbaudt, an autism advocate and author, has developed many resources for law enforcers and the ASD community; some of these resources can be found in the links provided above.

To conclude, youth with ASD do come into contact with the JJS; however, it seems that these contacts are not ASD-specific. With regard to factors associated with the JJS involvement, there appears to be a link between school-based offenses as well as fighting behavior at school, which may increase the risk of youth with ASD becoming involved in the JJS. Yet, the causal nature of these associations still needs to be

explored. Importantly, interactions with law enforcers can be extremely difficult for youth with ASD given certain characteristics of the disorder. Therefore, it is vital to understand youth with ASD and their families' experiences of the JJS in order to improve justice system interactions with individuals with the disorder and train law enforcers accordingly.

Suggestions for Law Enforcers

- It may be helpful to turn off police lights and cease sirens, as many youth with ASD are sensitive to bright light and loud noises.
- Avoid approaching the youth from behind.
- Avoid touching the youth, which could exacerbate sensory sensitivity.
- Outbursts or impulsive behaviors are not uncommon in autism. If no one is at risk of harm, wait for the behavior to decrease before continuing conversations with the youth.
- The youth may not respond to verbal commands; they may not understand the request or requirement, or they may be unsure how to respond in such a situation. Calmly and reassuringly, try again to communicate. You may have to repeat things multiple times or in different ways.
- Speak slowly and clearly, avoiding slang and sarcasm, which may be difficult for youth with ASD to understand.
- Using simple, plain language, pictures, or symbols may be more effective for communication.
- Allow time for the youth with ASD to respond to commands or requests (10–15 s).
- Check for an identification bracelet or autism handout card.
- If there is a parent, caregiver, or adult support with the youth with ASD, consider speaking to them first as they may be able to tell you the best way to communicate to the youth.
- Do not question youth with ASD without a support (e.g., caregiver, parent, legal guardian) present, as they may be easily influenced by others.
- When questioning the youth, keep in mind that many youth with ASD may:
 - Have difficulty with communicating and/or expressing themselves

- Respond more slowly than others their age
- Not understand verbal commands, especially if they are conveyed using metaphors, sarcasm, slang, or other imprecise terms
- Not understand nonverbal communications (e.g., head nods, hand signals)
- Be nonverbal
- Avoid making eye contact, while others with ASD may have very intense eye contact
- Try to hide their disability and not tell law enforcers that they have been diagnosed with ASD
- Try to run away
- Engage in repetitive behaviors (e.g., twirling objects, rocking, hand flapping,

pacing, talking to themselves), and this can worsen with stress

- Become upset with even slight changes to their routine
- Be interested in shiny objects such as your badge, keys, belt buckle, etc.
- Youth with ASD may need assistance filling out forms. You may have to offer general assistance or may have to read forms to the youth.

Suggestions for Caregivers

- Use an identification bracelet. It is not recommended that your child carries an autism identification card, as law enforcement may assume they are reaching for a weapon when the youth reaches for the card.

- Talk to your child about interacting with law enforcement and make a plan.
- Discuss disclosure of diagnosis to law enforcement.
- Make sure your child knows your phone number and home address or has this information with them so that they can contact you in an emergency.
- Make a plan for what you would want to communicate to the police officer about your child's diagnosis in case you are with your child during the interaction.
- Contact local disability agencies to help you create a plan.
- Think about developing community outreach programs to provide education to law enforcers and the chance for law enforcers to interact with the autism community.
- It may be helpful to provide your local police department with autism resources (e.g., brochures, handouts) so that they may become more familiar with autism in general.

Criterion

Juli Katon

Department of Special Education, University of Maryland, College Park, MD, USA

Synonyms

Benchmark; Measure; Standard

Definition

Criterion is a standard for minimally acceptable performance of a specific behavior or skill by an individual in order for the skill or behavior to be evaluated and judged as mastered. Criterion provides a defined and measurable answer to questions about how and when an individual has acquired a particular behavior or skill.

Criterion is one of three essential components of a behavioral objective, which is a mandated part of a student’s individualized education plan (IEP). A behavioral objective specifies a target behavior to be taught to a student, the conditions under which the behavior will be taught, and finally, the criterion, how mastery of the behavior will be assessed. An individual might be expected to perform a skill at a certain level of accuracy or

independence across a certain amount of days, number of times, or at a certain rate in order for the skill to be considered mastered. Choices about criterion are to be made based on the skill being taught. For example, an expectation of 80% accuracy may be acceptable in showing mastery of a math skill on a math quiz. However, 80% accuracy would not be an acceptable criterion for teaching an individual how to cross a street because this means that the student would be in danger of not making it across the street 20% of the time.

Definition

Criterion-Referenced Tests

Criterion-referenced tests are designed to assess whether an individual has a particular set of competencies or skills. They aim to answer questions such as “Is this child able to use a spoon for self-feeding or do up shoelaces?” or “Does this individual use sentences of four or more words or know how to subtract two numbers?” The focus of interest is the presence or absence of the criterion behavior and not, as in the case of norm-referenced testing, how the individual functions relative to some normative group.

Criterion-referenced measures may also be used to determine whether the individual meets the requirements for entry in special educational provision or for other decision processes. Psychiatric or other diagnoses are forms of criterion-referenced testing, the presence or absence of signs and symptoms of ASD constituting the criteria. Such uses of criterion-referenced test are sometimes known as “high-stakes testing” because of the major personal consequences of the outcome. In such uses in particular, including for clinical purposes, it is critical that the tests meet key criteria for quality (Kaplan and Saccuzzo 2009); that the tester is competent in administration, scoring, and interpretation of the test; and that the testee was functioning as they typically do.

Criterion-referenced items can function as norm-referenced measures. For instance,

developmental tests will have population norms on sentence length. Hence, a 5-year-old who has not yet achieved four-word sentences may be seen as being severely behind in their expressive speech compared with other 5-year-olds, whereas a 2-year-old with such skills would be seen as within the typical range of development for their age. Used in this way, they should be subject to the same quality standards noted for norm-referenced measures.

Definition

Introduction

Critical Autism Studies (CAS) is the only autistic-led community of practice, within autism studies,

and it has a few proposed definitions. A recent entry by notable autistic CAS scholars reviewed the main definitions and its ontology to propose a more inclusive approach between autistic and non-autistic academics; the preferred definition put forward is:

The ‘criticality’ comes from investigating power dynamics that operate in discourses around autism, questioning deficit-based definitions of autism, and being willing to consider the ways in which biology and culture intersect to produce ‘disability’. (Waltz 2014, p. 1337)

For a discussion on the other primary CAS definitions, see Woods et al. (2018). This essay outlines key concepts from disability studies and the nature of the neurodiversity movement before explaining how CAS is relevant to autism. The next section introduces disability studies and contextualizing core ideas with examples relevant to current debates in autism.

Disability Studies

Disability studies started in the 1960s (Woods et al. 2018) and grew out of disability activism (Barnes 2008; Goodley 2011; Oliver 2013; Thomas 1999), generating two terms and definitions that form a novel way of conceptualizing disability, instead of the dominant medical model of disability; these are impairment and disability. Impairment is viewed as the loss functional ability within a person due to the presence of either mental, physical, or sensory impairment. Disability is the loss of opportunities that an impaired person experiences due to physical and social barriers due that prevent living a normal life (Goodley 2011).

A focal point for disability campaigners is created by separating the biological aspects of impairment from the societal impact; it places the emphasis on adapting the environment to meet the needs of the individual. In this capacity the social model of disability is a tool for locating barriers and removing them. Like all tools, it has consequences to its use, as it can be blunt in application. By definition an impaired person’s family is also made disabled if they lose opportunities due to the impairment. For instance, if an autism parent has to sacrifice work to homeschool their child, the parent is made disabled. Some

suggest the social model is a threat to the medical model. Contrarily, the social model encourages the use of approaches from other disability models, especially if they remove barriers to impaired person's inclusion (Barnes 2008). For instance, the social model encourages the use of inclusive practices; for instance, if an autistic person requires augmentative and alternative communication (AAC) to participate in school activities, the AAC should be provided. Despite these positive aspects of the social model, it fails to explain the full nuances of lived experience, and therefore other ideas are required.

Exploring theoretical approaches to disability, Carol Thomas made significant strides in conceptualizing disability. One of Thomas' concepts is impairment effects, the loss of activities resulting from the impairment but not by disability as viewed by the social model. Thomas also developed disableism, as a form of oppression that involves restricting opportunities for impaired persons. The negative impact of such treatment on an impaired person's well-being is called psycho-emotional disableism (Thomas 1999). This can be viewed as part of the second wave of disability studies scholars. In contrast Fiona Campbell, approaching the cultural aspects of disability as part of Critical Disability Studies, coined ableism to investigate cultural structures and practices that reify the perfect human person; in the process impaired persons are viewed as diminished versions of this. Drawing upon critical race theory, Campbell proposed internalized ableism as the processes when parts of an oppressed (impaired) population demographic internalize discourses used to oppress them and then re-emit those discourses creating conflict between members of the oppressed group (Campbell 2008).

Disability studies scholarship is described as falling into a number of waves. The first-wave disability studies originated in the 1980s to the early 1990s, developing the social model and is a sociology derivative (Barnes 2008; Shakespeare 2017). The second wave focused on critique of the social model, investigating lived experience of disabled persons and drawing upon other discourses like feminism. Finally, the third wave, also known as Critical Disability Studies, focuses on the cultural processes contributing to disability

and thus drawing upon critical theory (Shakespeare 2017). However, one can view disability studies as being critical since its inception in the 1960s (Woods et al. 2018). Where CAS fits among these waves will be discussed later.

We have detailed core concepts and debates in disability studies. Now we highlight how their relevance to autism utilize the proposed autism subtype of pathological demand avoidance (PDA). The impairment would be high anxiety, and the impairment effects would be the demand avoidance. For internalized ableism, PDA is the oppressive discourse that is being accepted and expressed by some autistic persons. During the 1980s psychologists sought for traits that are switched off in autistic persons, while switched on non-autistic persons (Fletcher-Watson and Happé 2019). For PDA, the ability to comply with demands of everyday life and other's demands is severely impaired; nonetheless, non-PDA persons, the opposite is applicable. Thus, those who identify with PDA then re-emit the PDA discourse creating conflict within the autistic rights and neurodiversity movements.

For disableism, an example would be when an autistic female is denied an autism diagnosis due to the male bias diagnostic profile; and so some are suggesting PDA is a female form of autism (Gould and Ashton-Smith 2011), and it can be used to remove the barrier to an autism diagnosis for some autistic females. In contrast, PDA has been noted as a misdiagnosis for autistic females (Chown 2017). PDA highlights the complex and sometimes pluripotential nature of disability studies concepts when applied to autism.

As disability rights and disability studies became mainstream, the gains of the social model have receded (Barnes 2008; Oliver 2013). This is partly due to sustained academic challenge to the social model and to its adoption of a social model-light by disability charities (Oliver 2013). Since the 2007 financial crash, austerity measures concerted with disability legislation have eroded rights gained in previous decades, and the latter is used to police impaired persons. (Berghs et al. 2019). Berghs and colleagues (ibid.) went further to argue for a replacement of the social model, specifically a social model of human rights, to enable impaired persons to live full and

flourishing lives that the social model has failed to produce. Autistic persons counter that the social model was never fully implemented for all impaired persons, especially autistic persons (Woods 2017b). Such sentiments are supported by recent reports indicating autistic persons are being increasingly failed by society (All Party Parliamentary Group on Autism 2019). Precisely where autistic rights movement and how autistic persons are treated by society will be discussed in the neurodiversity section.

This section has introduced core terms in disability studies and its history. The discipline evolved from sociology and has drawn heavily from outside areas, such as feminism and critical theory. We provided examples of how these terms apply to autism by utilizing the proposed subtype PDA, such as how it is leading to internalized ableism among autistic persons. Finally, we discuss how the present treatment of impaired persons is leading to calls for a stronger social model of human rights.

Neurodiversity Movement

This year is the 20th birthday of neurodiversity, since Judy Singer's seminal essay in disability studies. The concept proposed is built upon the social model of disability where impairments like attention deficit hyperactivity disorder are perceived as natural variations of human diversity. Since then an entire movement has grown around the concept and it is primarily associated with autism, yet, it encompasses many other impairments. Indeed from its inception in the United Kingdom (UK), there have been substantial debates over conditions and thus who are encompassed by the term (Arnold 2017; Chown 2019a). Likewise, there is an ongoing debate over the strongest theoretical position, with a minority utilizing biological citizenship. This is based on genetic or biological citizens claiming rights on a diagnostic category or condition and is a medical model version (Runswick-Cole et al. 2016), not social model. Considering these contradictory outlooks, there are often intense clashes among supporters of neurodiversity.

There is a complicated relationship between neurodiversity and the wider disability rights

movements. This is reflected on how original disability rights movement focused on physical and sensory impairments (Chown 2019a). Although definition for impairment has been expanded to include mental impairments such those covered by neurodiversity movement (Goodley 2011), the social model is not practiced for mental impairments (Woods 2017b). Logically, those with mental impairments have since formed their own rights movement, which is often centered on the neurodiversity paradigm (Chown 2019a). Crucially, autistic rights movement and neurodiversity are separate and heterogeneous groupings with parallel endeavors (Woods et al. 2018). This variation between neurodiversity supporters is partly due to divergent developmental paths the movement has taken between the UK and North America (Arnold 2017). A problem situated to UK neurodiversity movement are the clashes between social model supporters and those who favor biological citizenship. The latter is favored by those who identify with the proposed form of autism, pathological demand avoidance (PDA) (Milton 2018).

Over the last several years, neurodiversity has been increasingly critiqued within the wider public (Den Houting 2019). Likewise the movement has come under sustained critique in CAS (Bolton 2018; Guest 2020; Runswick-Cole 2014; Runswick-Cole et al. 2016; Woods et al. 2018). CAS is a community of practice that overlaps second- and third-wave disability studies that focus on the autism impairment label. An earlier attempt to stop these straw man attacks on the paradigm seems to have failed. Thus, a more rigorous response is needed. We do not repeat previous dialogues on the debate, instead highlighting the positive contributions of neurodiversity to CAS. The next section explores how neurodiversity paradigm and its supporters have provided core literature to the intrinsic characteristics of CAS.

Current Knowledge

In order to explain how something has contributed to CAS, we need to know what its constituent traits are. The nature of CAS has been explored in a recent redefinition article, which posits CAS has the following characteristics:

CAS definition must be inclusive, be critical, allow new lines of inquiry and have epistemological integrity; the latter is important for the discipline's external acceptance. (Woods et al. 2018, p. 977)

We now explain and explore how neurodiversity supporters have provided key literature to these individual traits. First the article will explore these contributions that provide the critical component of CAS's name.

The origins of CAS are traced back to the birth of autistic self-advocacy, with Jim Sinclair's speech "Don't Mourn For Us" in 1993 (Woods et al. 2018). Sinclair challenges much of the pathologizing discourses about autism and 6 years before Judy Singer's seminal work. This indicates that autistic persons were looking for a movement to rally behind before neurodiversity existed. This view is in line with the historic position that those with mental impairments had not been included in the wider disabled persons movement. Pertinently, since 1999, many autistic persons resonate with the neurodiversity paradigm and have been actively involved in CAS since its inception at academic events almost a decade ago (Woods et al. 2018). Such individuals in 2012 launched the only CAS journal, *Autonomy, the Critical Journal of Interdisciplinary Autism Studies*. The role of this journal in CAS will be discussed later.

Over the last decade, numerous neurodiversity supporters have been challenging the medical model perspectives of autism. For instance, Melanie Yergeau has produced numerous key texts to CAS, where she critiques various concepts like theory of mind to the behaviorist-based intervention, Applied Behavioral Analysis (ABA) (2010, 2013, 2017). The primary motivation for such scholarship is to turn the source of problems experienced by autistic persons away from perceived faults located in autistic individuals and instead onto wider societal processes. Arguably, the most famous example is Damian Milton's double empathy problem that theorizes the communication issues experienced with autistic persons and is the result of a mismatch of saliences between autistic and non-autistic individuals (Milton 2017). This growing body of literature is pivotal to addressing the systemic

oppression faced by autistic persons (Woods 2017b), particularly considering the limited effectiveness of most autism strategies and interventions (Milton 2017). Ironically, the one intervention shown to be effective with high-quality evidence supports the double empathy problem, as it seeks to synchronize behaviors between carer and autistic infant (Pickles et al. 2016). Through such critical perspectives autistic scholarship is providing a turning point to empower themselves.

Autistic persons frequently are aware of the limitations and flaws found within autism studies. One such limitation is that of an academic silo; this is when the disciplines form their own communities of practice and so not understanding the potential contributions other disciplines can make. To assist in breaking down these barriers between silos, autistic persons founded the only CAS journal, the autistic-led journal *Autonomy, the Critical Journal of Interdisciplinary Autism Studies* (Arnold 2012). Many would note that there is a research-to-practice gap. However autistic scholarship has identified a theory-to-research-to-practice gap, with a lack of literature drawing upon autism cognitive theories (Chown 2017). Cross-pollinating disciplines are needed to help close the theory-to-research-to-practice gap by encouraging the use of broader theories in autism research.

Recently there are growing calls for participatory research on ethical and epistemic grounds (Milton 2017; Woods and Waltz 2019). Autistic research priorities tend to be in areas often overlooked by traditional research, such as support and services (Pellicano et al. 2014). Therefore, conducting inclusive research creates novel areas. Investigating the claims of a high-profile journal that we are in a new era of autism research, a preliminary study suggests that 3% of UK autism research is meeting autistic community wishes (Chown 2019b). With autistic persons being commonly unsupported, there is a pressing need for autism research to adopt an emancipatory ethos.

CAS scholarship contains many new lines of inquiry, not necessarily found in the main medical model-based literature, ranging from critique of

historically autism research being typically poor quality and unethically overstating the results (Dawson 2004; Milton 2017; Waltz 2007) to analyzing the activities of autism charities (Rosenblatt 2018; Waltz 2012). Pertinently, CAS draws upon third-wave disability studies by analyzing the cultural aspects contributing to autism. Important aspects include (1) drawing upon feminism, CAS seeks to explore the experiences of autistic persons through intersectionality (Saxe 2017; Strand 2017); (2) how autism is used as a Foucauldian biopower to control individuals (McGuire 2015; Moore 2019); (3) how the construct of autism is commodified into a form of control, frequently to the benefit of non-autistic persons (Runswick-Cole et al. 2016; Woods 2017a), for instance, how stigma around autism is intertwined with the processes that commodify the construct (Grinker 2020); and (4) to the cultural impact, negative medical model-based autism discourse, for instance, is a factor in autism mercy killings (McGuire 2016; Waltz 2008), often this is when a carer kills their child, in the vain hope of killing their autism (McGuire 2016). Through such novel authorship, CAS questions how biology and culture interact to construct the diagnostic category of autism.

There is growing evidence from autistic academics and the autistic population that all autistic individuals' mental health benefits from being in charge of their own lives, partially due to the pressures of conforming to societal demands (Milton 2017; Milton and Moon 2012; Stewart 2012; Woods 2017b). Autistic individuals also face additional societal pressures from psycho-emotional disableism (Milton 2013; Milton and Lyte 2012; Stewart 2012; Woods 2017b). For example, camouflaging is linked to suicidal ideation in autistic persons (Cassidy et al. 2018). Societal pressures contribute to the higher suicide rates and potentially higher rates of self-harming for autistic individuals (Maddox et al. 2017). It is clear that there is a growing momentum to act on the turning point CAS provides for autism studies to be autistic-led.

Neurodiversity supporters' perspectives are source of epistemic integrity to CAS; this is reflected in the growing evidence that

corroborates anecdotal views. Autistic persons often question behaviorist-based autism interpretations and interpretations (Dawson 2004; Milton 2017; Williams 2018; Yergeau 2017), especially aimed on behaviorist approaches that are typically used on vulnerable autistic children. Crucially, such critique is gaining more evidence (Harte 2019; Hassiotis et al. 2018; Kupferstein 2018). Autistic persons frequently challenge the accuracy of functioning-based labels and the negative effects they have for underestimating the challenges faced by all autistic persons. This has recently been supported by a large-scale quantitative study that indicates that IQ scores are an imprecise predictor of functional abilities (Alvares et al. 2020). Comparable observations from good-quality research noting how autism subtypes are clinically unstable and autism subtypes have similar prognosis (Happé 2011), thus supporting autistic preferences for a single diagnostic category (Fletcher-Watson and Happé 2019). The autistic autism theory, monotropism theory, is viewed by many neurodiversity supporters as the strongest autism theory (Woods and Waltz 2019). While it lacks direct empirical testing (Fletcher-Watson and Happé 2019), it is supported by emerging qualitative research (Bertilsson-Rosqvist 2019; Leatherland 2018; Wood 2019). Utilizing the strength of autistic perspectives is crucial to the integrity of autism and helping to improve the quality of life for autistic persons.

A central theme to CAS is the inclusion of autistic perspectives throughout the research process. A misconception of the neurodiversity movement is that it only represents those who are "high functioning." Contrastingly, one of its goals is to ensure all autistic persons (and their families) gain appropriate support (Den Houting 2019; Fletcher-Watson and Happé 2019). After all under the social model of disability, those around impaired persons are also made disabled by how society treats these vulnerable persons. Autistic persons are systematically oppressed. Consequently, this adversely affects autism parents through psycho-emotional disableism (Angell and Solomon 2017; Macleod et al. 2017).

There are numerous signs of this position. Firstly, neurodiversity supporters frequently

argue for the inclusion of all autistic persons' perspectives in autism research for epistemic and ethical grounds (Milton 2017; Woods and Waltz 2019). Secondly, social model supporters have developed inclusive methodologies for underrepresented autistic demographics, including those with learning disability, such as by Bertilsdotter-Rosqvist et al. (2019), Nicolaidis et al. (2019), Ridout (2014, 2016), and Stewart (2012). More recent inclusive methodologies are seen in CAS by other scholars; see Andrews et al. (2019) and Macloud (2019). Thirdly, the National Autistic Taskforce is composed of many neurodiversity supporters, and it is a body specifically seeking to address shortcomings in practice for autistic persons and learning disability. Fourthly, neurodiversity inclined networks, like the Participatory Autism Research Collective, hold annual conferences, in part to provide a platform for those who would not typically be heard. Through such practices, neurodiversity supporters are seeking to remove social barriers to the inclusion of all autistic persons.

One key notion when considering inclusiveness, which is key to CAS, is the recognition of the role of power. As aforementioned, there is an increasing number of autistic scholars and a growing number of publications; autistic academics "upset the apple cart" in terms of power and further complicate notions of power and whose position is more dominant, as autistic people normally considered to be passive participants in research or assessment (Milton et al. 2019), rather than directing their own scholarship. This is fitting with the intersectional nature of current movements including fourth-wave feminism (Evans 2013, p. 7) and, more notably in this case, the autistic civil rights movement (Pountney 2018). Against the backdrop of postmodernist notions of identity and being, we can truly appreciate the importance of examination of power in inclusive research. The Participatory Autism Research Collective and the current drive for "inclusive participatory research" from scholars and activists alike (e.g., Bertilsdotter-Rosqvist et al. 2019; Chown et al. 2017; Fletcher-Watson et al. 2019) have called for reflexivity of standpoints from scholars and researchers, which is applicable to

and necessary in CAS. Furthermore, examination of power and its impact on inclusion allows for further lines of inquiry to be considered, for example, who may define what "good quality of life" is for an autistic person (Waldock 2019) and whose agenda is being served (as discussed in Milton 2017). This demonstrates the importance of recognizing power as part of the inclusive dimension of CAS.

This entry has explored what Critical Autism Studies is and contextualized the background to this growing discipline of autism studies. Initially exploring key points of the derivative of sociology, Disability Studies that CAS heavily draws upon. Subsequently, we discuss the nature of the neurodiversity movement and how this is both separate to and mutually supporting the autistic rights movement. In the final section, we detail how autistic academics have played a leading role to the emergence of CAS and their importance to the constituent parts of the discipline, "critical, allow new lines of inquiry and have epistemological integrity" (Woods et al. 2018, p. 977). In the process we highlight the importance of CAS as being the only discipline of autism studies to be autistic-led due to the involvement of neurodiversity supporters.

Due to the myriad of topics covered in CAS, it is not possible for us to provide more than this descriptive overview of the discipline, and we encourage readers to explore the recommended reading. Moreover, with the growing trend away from tokenistic autism research, by its nature as an autistic-led discipline, it will continue to gain traction in wider autism studies; in the process, it helps to break down the barriers between academic silos common in broader scholarship (Arnold 2012). Future directions for the discipline are likely to focus on inclusive research practices, questioning pathologizing conceptualizations of autism and thus being the pivot for improved quality of life for all autistic persons.

Cronbach's Alpha

Ellen Johnson

Section of Social Work, Mayo Clinic, Rochester, MN, USA

Synonyms

Coefficient alpha

Definition

Cronbach's alpha (α) is an estimate of reliability, specifically the internal consistency, of a test or scale. It is widely used in psychological test construction and interpretation (Cortina 1993). When internal consistency is present in a test, it is interpretable (Cronbach 1951). Cronbach's alpha seeks to measure how closely test items are related to one another and thus measuring the same construct.

The formula for Cronbach's alpha is as follows:

$$\alpha = (n/(n - 1)) \times (1 - (\sum s_i^2 / s_T^2))$$

where n is the number of items, s_i^2 is the variance of the i th item, and s_T^2 is the total score variance (Cronbach 1951).

When test items are closely related to one another, Cronbach's alpha will be closer to 1, and when test items are not closely related to one another, Cronbach's alpha will be closer to 0. An α of 0.90–0.95 is desirable for clinical interpretation of tests (Bland and Altman 1997).

Crystallized Intelligence

Francesca Happé
MRC Social, Genetic and Developmental
Psychiatry Centre, Institute of Psychiatry,
Psychology and Neuroscience, King's College
London, London, UK

Definition

Crystallized intelligence (abbreviated Gc) is reflected in a person's general knowledge, vocabulary, and reasoning based on acquired information. It is contrasted with fluid intelligence (see ► [“Fluid Intelligence”](#)) as one of the two factors of general intelligence first proposed by Cattell (1971). Crystallized intelligence is conceptualized as the product of experience, both cultural and educational, in interaction with fluid intelligence; people with higher levels of fluid intelligence will

generally amass learnt information faster, allowing higher crystallized intelligence. Crystallized intelligence is measured by tests such as vocabulary and general knowledge type assessments.

In ASD, the profile of better performance than verbal IQ subtest scores may reflect, in part, differences between fluid and crystallized intelligence. It has been suggested that standard IQ assessments underestimate intelligence compared to pure fluid assessments such as Raven's Progressive Matrices (Dawson et al. 2007). The acquisition of skills and knowledge, as measured by crystallized intelligence tests, may rely in part on socially mediated learning and be hampered in ASD by problems of social cognition (Scheuffgen et al. 2000). However, Bölte et al. (2009) suggested that discrepancies were small among higher functioning ASD groups and recommended use of Wechsler intelligence scales for comprehensive assessment of abilities in ASD, perhaps supplemented by Raven's Matrices for lower functioning individuals. Recent estimates from epidemiological samples suggest that low measured IQ is not as common among people with ASD as previous figures suggested; Charman et al. (2011) reported just over half their community sample of young people with ASD had IQ below 70, with less than a fifth having IQ below 50, and almost a third of the sample having IQ above 85. Improvements in understanding, recognition, and intervention may have improved accessibility of appropriate education for children with autism, allowing more individuals to come closer to fulfilling their learning potential.

Description

Children with an autism spectrum disorder (ASD) form a heterogeneous group. The Children's Social Behavior Questionnaire (CSBQ) charts this heterogeneous behavior through 49 items rated by parents. These items are scored on a three-point scale ranging from “does not apply or occur” to “clearly or often applies.” Items refer directly to DSM-IV criteria for autism but also represent less severe variations of these criteria as well as ASD-associated problems,

such as executive functioning problems and disruptive behavior in difficult social situations. The 49 items aggregate into six problem dimensions which form the subscales of the CSBQ. Children with ASD tend to vary in the extent to which the problems captured by these subscales are present; therefore, each child has his or her own problem profile.

Subscale names are abbreviated as social, tuned, understanding, orientation, change, and stereotypies and capture the following problems:

- First, the subscale “social” measures aspects related to social contact, social interest, and social reciprocity. It refers to both initiation of contact and reaction to social overtures by others.
- Second, the subscale “tuned” measures behavior related to daily adaptation to social situations. Examples of items are as follows: “overreacts to everything and everyone” and “does not know when to stop, goes on and on about things.” While instances of such behavior may also be seen in typically developing children, the tuned subscale depicts the more extreme form manifested by children with ASD.
- Third, children with high scores on the subscale “understanding” have difficulties in understanding the rules of communication and the social use of language (pragmatic communication). Sample items are as follows: “does not understand jokes” and “is extremely naive; believes anything you say.”
- Fourth, the orientation subscale refers to the ability to keep an overview of what goes on, what one is doing, and where one is headed. Sample items are as follows: “gets lost easily” and “has difficulties doing two things simultaneously.”
- Fifth, the items of the subscale “change” measure behavior when confronted with changes, expressed as fear, panicking, resistance, and freezing.

Sixth, the items from the stereotypies subscale tap the various repetitive sensorimotor behaviors seen in children with ASD such as making odd

movements with fingers and hands, smelling objects, and being unusually sensitive to certain sounds.

Both total CSBQ score and individual subscale scores can be used. The profile of scores on the six dimensions simultaneously reveals which problem domains are predominantly present in the child and which problem domains are less prominent. The subscales “orientation” and “tuned” are not specific for ASD, with similar scores in children with ADHD. Thus, if the aim is to focus specifically on the most differentiating ASD core symptoms, scores on the subscales social, understanding, change, and stereotypies are summed.

Historical Background

Parent-report questionnaires are cost- and time-efficient assessment tools in health practice and research. The research program to develop the CSBQ started for two reasons. First, the goal was to quantify the different dimensions on which children with an ASD tend to differ, thus tapping the heterogeneity in this group. The second goal was to specifically include the milder part of the ASD score distribution along with the more severe autistic behaviors in one and the same instrument, thus tapping the full ASD spectrum. The field lacked a questionnaire that tapped not only the severe behaviors seen in autism proper but also these milder and subtler variants of ASD. The inclusion of these (in addition to the more severe autistic behaviors) in an instrument would be helpful in the diagnostic process of ASD, and even in case of a diagnosis outside the ASD spectrum, knowing the presence of such mild problems would be useful. Moreover, the field lacked a questionnaire that summarized the heterogeneous problems seen in ASD by a number of meaningful problem dimensions along which children with an ASD show variation. The peaks and troughs on a profile of different ASD problems would give insight into children's specific clinical presentation within ASD and provide clues for intervention.

With these ideas in mind, the CSBQ was developed about 15 years ago (Luteijn et al. 1998).

In its original form, the CSBQ contained 96 items. Revised in 2006, the 49-item CSBQ gained in specificity by removing problem items that were only marginally characteristic of ASD (Hartman et al. 2006). Instrument development is still in progress. For example, an adult counterpart of the CSBQ, the Adult Social Behavior Questionnaire (ASBQ), with both a self- and other-report version, has been developed and currently is being validated (Horwitz et al. 2012).

Psychometric Data

CSBQ scores are interpreted in relation to norm groups. Norms are available for boys and girls and for six age groups between ages 4 and 18 for children from the general population. Gender-specific norms are also available for general psychiatric child (4–11) and adolescent (12–18) population. From the general psychiatric population, separate norms are available for three subgroups: ADHD, PDD-NOS, and higher functioning autism, respectively. Further, there are norms for children (4–11) and adolescents (12–18) with mild mental retardation and for children (4–18) with moderate mental retardation. These groups are split up further into separate norms for children with both mental retardation and ASD (Hartman et al. 2007).

Several factor analytic studies with varying item pools indicate that the six ASD problem dimensions that are differentiated by the CSBQ are firmly anchored in the data (Hartman et al. 2006; Luteijn et al. 2000a). That is, the ASD problem dimensions emerging from the original item pool of 96 items and from the revised version with the 49 items are highly similar. Additionally, the ASD problem dimensions emerged from a simultaneous factor analysis of the CSBQ with Child Behavior Checklist items. The consistency in factor structure speaks to the construct validity of the problem dimensions.

Multiple studies have shown that the CSBQ has good psychometric properties with regard to test-retest and interrater reliability, internal consistency of the scales (all reliability indices at least .75), and good criterion validity both for

high-functioning children and for children with mild to moderate mental retardation (de Bildt et al. 2005, 2009; Hartman et al. 2006; Luteijn et al. 2000a, b). The CSBQ differentiates between autism and PDD-NOS on the one hand and PDD-NOS and ADHD on the other hand, with decreasing scores for these three conditions, respectively (Hartman et al. 2006). The differences between these diagnostic groups come mostly from the four core autism problem dimensions, i.e., social, understanding, change, and stereotypies. Note however that a combined diagnosis of ADHD and ASD is accompanied by significantly higher scores on the tuned and orientation dimensions than a separate diagnosis of either ADHD or ASD, suggesting that each condition has its own impact on the behaviors measured by these scales (Hartman et al. 2006). Further indices of criterion validity are an association of .75 for the CSBQ with the Autism Behavior Checklist (Krug et al. 1980; Hartman et al. 2007) and associations of around $-.40$ for relevant subscales with Theory of Mind ability (Blijd-Hoogewys et al. 2008). For children with mental retardation, the CSBQ distinguishes between the profiles of the PDD group and the non-PDD group (Hartman et al. 2006). A second study in children with mental retardation showed that the contribution of the CSBQ to a classification of ASD was most specific for the problem dimensions "contact" and "stereotyped," with high coherence with classification methods of ADI-R, ADOS, and clinical DSM-IV-TR classifications.

For research purposes, the instrument has proven useful in genetic (Nijmeijer et al. 2010a, b, 2011), neurocognitive (Geurts et al. 2008; Rommelse et al. 2009), and behavioral (de Bildt et al. 2005; Luteijn et al. 2000c) studies, thus adding to its validity. For example, Nijmeijer et al. showed that the COMT Val/Val genotype interacted with maternal smoking during pregnancy in increasing stereotyped behavior in two independent samples. As a second example, in a sample of 816 children from ADHD and control families, executive functioning and motor impairments were correlated and cross-correlated in siblings to autistic traits, suggesting that ADHD and ASD may possibly share familial/genetic EF and motor deficits. The CSBQ has also aided in characterizing (subthreshold) ASD problems in

populations other than ASD such as ADHD (Nijmeijer et al. 2008) and delinquent groups (Geluk et al. 2011; 't Hart-Kerkhoffs et al. 2009). Finally, early childhood assessments by community pediatric professionals were predictive of CSBQ ratings during adolescence (Jaspers et al. 2011).

Clinical Uses

The CSBQ may be used as a signaling, screening, or describing instrument for children aged 4–18 and for all levels of functioning. Scores on the CSBQ can be interpreted relative to norms based on the general populations or 3 norms based on general child psychiatric outpatient groups as well as on specific psychiatric groups such as autism or ADHD. Norms vary according to age, gender, and level of functioning.

In the orienting stage of the diagnostic procedure, the score profile of the six subscales contributes to identifying whether or not the problem behavior of the child is suggestive of ASD and whether further diagnostic assessments should be focused on ASD.

Additionally, the CSBQ may be of value further in the diagnostic process, clearly not in diagnosing ASD (which should be based on a more extensive diagnostic procedure including observation and interviewing) but in complementing these methods by adding additional information about the child's clinical profile of problems along the six CSBQ problem domains. This profile reveals the child's major ASD problem areas as well as the domains that follow normative development. This may add to the diagnostic process as well as direct treatment choice.

In children with a diagnosis outside the ASD spectrum, the CSBQ may reveal the presence of subthreshold ASD problems which may be helpful for choice of treatment.

Haven, CT, USA

Synonyms

[Cerebrospinal fluid 5-hydroxyindoleacetic acid](#)

Definition

Cerebrospinal fluid (CSF) levels of 5-hydroxyindoleacetic acid (5-HIAA), the principal metabolic end product produced from the neurotransmitter serotonin, are measured to provide a global index of serotonin production in the brain. Taken together, studies of CSF 5-HIAA in autism indicate that group mean levels are not altered in autism.

Culturally Responsive Assessment of Language and the Challenge Within Standardized Tests

Julie Bender¹, Erin Gelinis¹, Nicole Fischer¹ and Barbara A. Cook²

¹Department of Communication Disorders, Southern Connecticut State University, New Haven, CT, USA

²Department of Communication Disorders, Center of Excellence on Autism Spectrum Disorders, Southern Connecticut State University, New Haven, CT, USA

Definition

Cultural responsiveness is an aspect of quality assessment and education that requires being aware of the cultural differences that may affect one's knowledge and consciously adapting to ensure that each child is being accurately assessed and is being taught in a way that is both relevant and effective with respect to their culture (Gay 2000).

Historical Background

Practitioner competence in the use of cultural responsiveness would result in quality assessment and indicate being aware of the cultural

differences that may affect performance, thus lead to consciously adapting evaluation protocols to ensure that each child is being accurately assessed in a way that is both accepting and respectful of their culture (Paul et al. 2018). Evaluation protocols that include assessment batteries that are not culturally responsive have the potential to overdiagnose language disorders in individuals who are culturally diverse (Paul et al. 2018). Culturally diverse children may have language differences, which are styles of language that are different from the standard language of one's culture, yet still follow a rule-governed style (Paul et al. 2018). If an individual has a language difference, it does not imply that this individual has impairment in the ability to learn language nor should they be diagnosed with a language disorder. An individual with a language difference has the capacity to learn the standard language after simply being exposed over time, whereas, individuals with language disorders have impairments that typically require intervention in order to meet social and academic expectations (Paul et al. 2018).

Alternatively, a lack of cultural responsiveness by practitioners can result in the delay of a diagnosis of some developmental disabilities such as Autism Spectrum Disorder. Those of different cultures may lack knowledge of the subtle cues or signs relating to Autism Spectrum Disorder (ASD) and view these changes as a normal process that occurs for all developing children (Danescu 1997). This can impact when or if the child is referred to professionals to then be assessed. For example, socioeconomic status and one's background does not dictate whether or not a child has autism, but may contribute to a physician's decision to screen for ASD (Gibson 2007). As a result, the socioeconomic status of children may cause a delayed diagnosis for certain individuals, especially for African American children. These children are 2.6 times less likely to receive a diagnosis of autism compared to their Caucasian peers (Mandell et al. 2007). Therefore, it is important for practitioners to be aware of these potential culturally related biases and be prepared to proactively reach out to the community to assist in reducing the disparity of diagnosis that occurs (Wiggins et al. 2019). Further, the disparity of

diagnosis of autism in culturally diverse individuals can likely be further confounded when utilizing assessment protocols that are inconsistent with their responsivity to diverse cultures.

In an effort to better understand the degree of cultural responsiveness of a few commonly used test batteries for the development of language, and potentially as they are used as part of a comprehensive evaluation for possible diagnosis of ASD, this review of literature explores the following instruments: Communication and Symbolic Behavior Scale (CSBS), Diagnostic Evaluation of Language Variation-Norm Referenced (DELV-NR), Clinical Evaluation of Language Fundamentals Preschool-2 (CELF-P2), Token Test for Children-Second Edition (TTFC-2), and the Preschool Language Scale-Fifth Edition (PLS-5). The question of the likelihood of overdiagnosing culturally diverse children with language disorders when using these test batteries is explored. The information provided will serve as an initial step in providing knowledge to support use of cultural responsiveness by clinicians as they use these test batteries to assess the language skills of culturally diverse children and those who present with ASD.

Current Knowledge

CSBS

The Communication and Symbolic Behavior Scale assesses the social, communicative, and symbolic abilities of children. It was created for children between the ages of 8 months and 2 years. This assessment is comprised of the Caregiver Questionnaire which collects information about the child's communicative skills, the Behavior Sample, a play-centered method of collecting data that is videotaped for scoring, and the Caregiver Perception Rating form. This form is filled out by the caregiver after observing the Behavior Sample and collects information on how often the child typically exhibits the behavior revealed in the sample. This assessment battery includes toys and books to elicit spontaneous communication. The CSBS is useful in a natural environment to observe a child's play and communicative skills (Wetherby and Prizant 2003).

A shortened version of the CSBS is the CSBS DP: The Communication and Symbolic Behavior Scales Developmental Profile. This was created to be more efficient than the original version.

The CSBS DP has been identified as an assessment tool that can be used cross-culturally with relatively consistent outcomes. In 2016, there were no standardized tests to assess early social communication skills in South African (SA) children (Chambers et al. 2016). The scores of 67 English-speaking South African children on the CSBS DP Behavioral Sample were compared to the standardized scores. The researchers found that from 15 months of age there seemed to be little bias for, or against, SA subjects compared to those in the United States. Based on these results, the researchers concluded that the CSBS DP was culturally fair in assessing South African children from different cultural backgrounds (Chambers et al. 2016). However, the score on the Words cluster subtest revealed differences between children who were monolingual and those who spoke more than one language, with the children who spoke multiple languages scoring lower on the Words cluster section. Yet their scores were still within the limits of the assessment. The toddlers in the SA sample performed well on the gaze tasks, but not as consistently as those in the US groups. As stated previously, this finding may be because of a difference between the cultures being compared. It is possible that the children from the SA sample are more reserved than those from the US sample (Chambers et al. 2016).

Similarly, Roberts et al. (1997) suggest that the CSBS DP is helpful in detecting communication delays in children who are outside of the standardization sample. They assessed 93 African-American 1-year-old children, the majority of them living below poverty level. The results were similar to those of the standardized sample, with the exception of gestural means, which was lower than those of the children in the standardized sample. There are a number of reasons this could be, including differences in how the African-American culture uses gestures or the differences in parents' interaction. The overall results of this group were similar to those of the standardized sample, thus supporting that the

standardized sample is fairly representative cross-culturally (Roberts et al. 1997).

Alternatively, Tek and Landa (2012) argue that the CSBS may not be sensitive enough to cultural differences. When comparing 19 minority toddlers to 65 Caucasian toddlers, the CSBS Caregiver Questionnaire was used. The minority children in this study showed more atypical language and communication scores than their non-minority counterparts, especially on the CSBS Words and the CSBS Understanding of Words. The researchers concluded that minority parents may not view certain behaviors or delayed milestones as concerning, relating to a gap in scores. For example, in some Asian cultures, eye contact with elders is considered disrespectful and a lack of eye contact will result in a lower score on the CSBS Social Composite section. A cultural difference must be determined here so that a child is not wrongly scored. This study was largely made up of children from the upper middle class, independent of ethnicity, so it would be important to compare minorities from a lower class as well (Tek and Landa 2012). Overall, the CSBS is a promising tool for groups that it was not standardized on, and the research thus far shows that it is a culturally responsive assessment tool.

DELV-NR

The Diagnostic Evaluation of Language Variation-Norm Referenced (DELV-NR) is an assessment used to language skills within the domains of phonology, semantics, syntax, and pragmatics of children between the ages of 4 and 9 years, 11 months who speak English as their primary language yet a dialect that is considered varied from Mainstream American English (MAE) (Seymour et al. 2018, p. 1). The DELV-NR can be used to diagnose children with speech and language delays or disorders, and to differentiate delays and disorders from language differences that are seen in dialects other than MAE. Test materials for the administration of the DELV-NR include a stimulus book with colored images as well as a response form. Each domain of language is assessed using multiple subtests and administration of the entire test takes approximately 45 min. Scores can be used to determine

a percentile rank in each domain as well as to diagnose a language or speech disorder.

To limit the impact of cultural bias on the test results of culturally diverse children, the DELV-NR clearly distinguishes features of English that are found in every dialect from features that differ between English dialects and focuses only on the universal features of English dialects. By doing this, it creates a dialect neutral assessment that limits the ability for speaking a dialect other than MAE to impact test results. Therefore, results on the DELV-NR clearly distinguish between a language difference and a disorder. This assessment filled a gap in the available resources for the assessment of children who are culturally and dialectically diverse, and it addressed a significant weakness that is present in many other assessment materials.

Many assessments lack test materials that use only the aspects of language that are universal across all dialects of English. This can lead to struggles in distinguishing language differences from language disorders as many children who speak English dialects other than MAE receive low scores on these assessments. While children may provide responses that are grammatically correct in their dialect, it could result in lower scores if it does not match the desired response in MAE. This often leads to the overdiagnosis of dialectically diverse children, which could lead to unnecessary speech and language services being provided (Losen and Orfield 2002; Robinson and Norton 2012).

One study found that the DELV-NR was able to provide a detailed summary of children's language skills that were highly consistent with their spontaneous speech language samples. They also concluded that the DELV-NR can help improve the quality of assessment and diagnostic accuracy of language impairments in dialectically diverse children (Pearson et al. 2014). Additionally, because the DELV-NR was normed on 900 children who were representative of the demographic diversity of the general population of the United States based on the 2002 U.S. Census, its diagnostic criteria is relevant for speakers of diverse English dialects as well as speakers of MAE (Seymour et al. 2018, p. 109).

By establishing a test that focuses on using the aspects of language that are universal across all dialects of English, the DELV-NR is able to distinguish language differences from disorders with greater accuracy and minimize the overdiagnosis of language disorders in children (Pearson et al. 2014).

CELF-P2

The Clinical Evaluation of Language Fundamentals Preschool-2 assesses morphology, phonology, syntax, semantics, and pragmatics in children ages 3–6 years, 11 months. In this assessment, children respond to picture stimuli in an easel style book, by either verbally responding or pointing. Identifying a language disorder or delay that has a negative impact on a child's success in the classroom is a goal of this assessment. The normative sample of 1500 preschool aged children was representative of the United States population at the time of its creation in 2002. 62.1% of the normative sample was white while 37.9% was non-white. It is important to note although the normative sample would have changed since 2002, it is representative of the population at that time (Wiig et al. 2004).

The CELF-P2 UK is a version of this assessment used in the United Kingdom and it is one of the most widely used standardized assessments in that nation. Similar to the USA, it is maintained that children in the UK who come from disadvantaged backgrounds are more likely to have language delays than those from privileged communities (Ryan et al. 2016). Additionally, a Spanish version of the CELF-P2 has been developed. The norms for this battery were created based on a range of children from culturally, racially, and ethnically different backgrounds. Although not included in the CELF-P2, it is notable that in the fourth revision (CELF-4), there is a section in the manual discussing the influences of African American and Spanish cultures (Paslawski 2005).

Current research suggests the CELF-P2 as mostly culturally responsive. For example, children adopted from Eastern Europe between the ages of 1 and 4 years, 11 months were assessed on the CELF-P2 with Russian, Hungarian, or

Romanian as their first language. The scores of these children were within average range for both expressive and receptive language, displaying cultural relativity with minor language differences not effecting scores. Therefore, this assessment can be appropriate to use on children from different cultures, assuming that they can understand English (Glennen 2015).

In another study examining Aboriginal Australian children, the children who used Aboriginal English performed well on the CELF-P2. The use or lack of use of Aboriginal English did not predict children's performance on the CELF-P2 language sample portion. An explanation for this could be either the assessment tool is not sensitive enough to the differences between Aboriginal English and Standard Australian English, or that the children are code-switching. Overall, it is determined that this is an appropriate assessment to use for children in the early language development stages (Miller et al. 2014).

TTFC-2

The Token Test for Children-Second Edition (TTFC-2) assesses receptive language difficulties in children ages 3–12 years, 11 months. Scores from this assessment reflect the child's ability to complete multiple-step oral directions, understand expressive language, and use their short-term auditory memory. The linguistic components assessed include syntactic structures, knowledge of prepositional and relational concepts, and semantic development. The TTFC-2 includes contextualized stimuli of 46 verbally transmitted commands divided into four parts based on their complexity level, allowing measurements to concretely reflect the child's receptive language and not rely on verbal expression (DiSimoni et al. 2007).

The original TTFC efficacy for evaluating children has not been promising due to its lack of age norms, socioeconomic group comparison and lack of clarity in data collection (DiSimoni 1978). This led to the creation of the TTFC-2 in 2007 by DiSimoni, Ehrlet, and McGhee, which showed improvement from the first edition in validity, reliability, and normative data by having it be a diverse representative of the demographics

of the current United States population. The standardization of the TTFC-2 was based on of geographically diverse communities which included minorities such as those who identify as African American, Hispanic, Asian, and Native American. However, the sample for standardization failed to provide socioeconomic status.

The format of the TTFC-2 assessment holds clinical value for diverse cultural linguistic communities. Several versions have been developed such as Dutch, German, Khmer, Kannada, Polish, Portuguese, and several Spanish-speaking populations (Gallardo et al. 2011). Although many versions lack standardization and psychometric evidence, resulting in poor efficacy, there are two versions that do hold validity and reliability. The A-TTFC was created for native speakers of Arabic (Alkhamra and Al-Jazi 2016) and presents as a valid and reliable assessment. The test was changed into an appropriate Arabic format without adjusting any content and measures of the TTFC and presents with similar clinical strengths for Arabic-speaking children as the TTFC-2 does for English-speaking children. The Revised Token Test (RTT) has shown to be a reliable and valuable tool for assessment for Spanish-speaking children due to its psychometric sensitivity. Spanish speaking children are the most frequent ethnic group receiving services from speech-language pathologists, so it is important to have a reliable assessment for this population in order to avoid under referrals or over referrals (Roseberry-Mckibbin and Eicholtz 1994). Although this revised assessment has shown to result in valid results, additional research is needed with the normative data for these revisions before relying on these versions of assessments throughout practice.

PLS-5

The Preschool Language Scales, Fifth Edition (PLS-5) is used to evaluate the domains of Auditory Comprehension (AC) and Expressive Communication (EC) in children from birth to the developmental age of 7 years, 11 months. This test assesses several domains including: “attention, gesture, play, vocal development, social communication, vocabulary, concepts, language

structure, integrative language, and emergent literacy” (Zimmerman et al. 2011). The results of this test can be used to determine areas of difficulty and strength, and to track the child’s progress over time. The results of this test can identify if the child has a language delay or language disorder, and if it is expressive, receptive, or both. The PLS-5 provides norm-referenced scores for both the AC and EC sections. Additionally, it provides the information necessary to calculate a Total Language score. Based on the standard score that the child receives, the clinician can determine the distance from mean, percentile rank, and age equivalent for that child. These scores can help determine where the child’s communication skills fall compared to other children of the same age (Zimmerman et al. 2011).

The PLS-5 accounts for dialectical differences by providing correct responses for the dialects of African-American English, Appalachian English, English influenced by Chinese languages, English influenced by Spanish, and Southern English. This decreases the likelihood that children will be penalized for speaking with a dialect other than Standard American English provided the clinician is aware of the dialectical difference and references the applicable correct responses.

While there are several benefits of using this test battery, there are also cultural and environmental limitations that have been indicated. For example, when using this assessment on Mandarin-speaking children, most of the 4-year-olds were unable to express what they would do with a coat, towel, or cup, and nearly half of the 3-year-olds were unable to answer the questions about what they would do if they were sick (Ren et al. 2016). In this culture, it is rare for children to be encouraged to participate in self-care tasks, which could negatively affect their performance on sections of this test battery and lead to the over-referral of children from this culture. Additionally, factors such as socioeconomic status or prior exposure to stimuli could affect performance on this assessment. There is evidence that children from low socioeconomic status may perform more poorly on vocabulary tasks than children from higher socioeconomic status homes due to

lack of exposure, even though the ability to learn new vocabulary is not impaired (Horton-Ikard and Weismer 2007). These limitations could lead to the overdiagnosis of culturally diverse children with language disorders in expressive language and auditory comprehension of language and lead to providing treatment services to individuals who do not need these services, unnecessarily taking up the time of both the student and the clinician.

Future Directions

Many assessment batteries that are commonly used in the United States for the assessment of language skills and the diagnosis of language delays and disorders in children have cultural limitations that could potentially lead to the overdiagnosis of culturally diverse children (Horton-Ikard and Weismer 2007; Losen and Orfield 2002; Pearson et al. 2014; Robinson and Norton 2012; Roseberry-Mckibbin and Eicholtz 1994). This initial review of literature has examined the cultural limitations in the commonly used test batteries and reveals the necessity to continue to explore standardized measures for their degree of cultural sensitivity and responsiveness.

While some assessment tools, such as the DELV-NR (Seymour et al. 2018), were designed to be dialectically neutral to improve the diagnostic accuracy of language disorders in this population, other commonly used assessments were found to have weaknesses that could lead to the overdiagnosis of children who are culturally diverse. As the world is becoming more culturally responsive, our language assessments must follow suit. Looking ahead, clinicians must be vigilant in responding to the differences presented by children and acknowledge cultural differences prior to the administration of an assessment. Miller et al. (2014) suggest using language assessments with other language analysis methods that are culturally appropriate. Further, they suggest that speech-language pathologists should be sensitive to the varied cultures and languages that children are exposed to and not make any assumptions regarding their culture and the impact on their language comprehension and expression (Miller

et al. 2014). Lack of awareness of these weaknesses is clinically relevant and could lead to providing services to individuals who do not require intervention or result in a child being delayed in receiving services. A culturally responsive clinician should be aware of the degree of cultural bias in the test batteries they are using to evaluate their clients in order to accurately assess the language skills of culturally diverse children and provide services only if they are necessary (Paul et al. 2018).

Development and Employment Support Center,
New Life Psychiatric Rehabilitation Association,
Kowloon, Hong Kong

Definition

The CBT-context-based social competence training for ASD (CBT-CSCA) was a social competence training specifically developed for Hong

Kong Chinese adolescents with ASD. The CBT-CSCA was grounded on cognitive-behavioral therapy and incorporated cultural-sensitive elements. It demonstrated the effectiveness in improving social competence among adolescents with ASD in Hong Kong, and the gains were sustained 3 months after the training.

Historical Background

Impaired social functioning is a hallmark feature of autism spectrum disorder (ASD). It becomes a defining feature in the current diagnostic approaches (American Psychiatric Association; APA 2013). Despite improvements shown in other features of ASD upon interventions, social difficulties persist as individuals enter adolescence and young adulthood (Schall and McDonough 2010). This persistence is possibly due to a rapid change in the social landscape and the increase in the complexity of social interaction during adolescence.

In the lack of the necessary social skills to handle complex social situations, adolescents with ASD tend to suffer from a number of negative consequences, including restricted social circle, peer rejection, and bullying (Rieffe et al. 2010). Without pleasant social experiences, adolescents with ASD also suffer from a high prevalence of psychiatric disorders (Simonoff et al. 2008). Presumably, equipping adolescents with ASD with appropriate social skills improves their social deficits as well as their comorbid psychiatric symptoms. Addressing the critical socialization needs of adolescents with ASD, there has been a rapid increase in research on social competence interventions for adolescents with ASD since the previous decade (Reichow et al. 2013).

Group-based intervention has demonstrated initial success (Miller et al. 2014), such as the Program for the Education and Enrichment of Relational Skills (PEERS) (Laugeson et al. 2012), the Multimodal Anxiety and Social Skills Intervention (MASSI) program (White et al. 2013), and Skillstreaming (Lopata et al. 2008). However, most studies published are designed and validated in the Western culture, such as the

USA, Germany, and Scotland, limiting their generalizability. Studies in the East included only the validation studies of the PEERS in Korea (Yoo et al. 2014) and Hong Kong (Shum et al. 2019).

Current Knowledge

In light of the distinctiveness of Chinese culture as compared to the West, the CBT-context-based social competence training for ASD (CBT-CSCA) was developed locally to cater the unique cultural and service needs for Chinese adolescents with ASD. The CBT-CSCA followed the definition of social competence suggested by Bierman and Welsh (2000) “an organisational construct that reflects the child/adolescent’s capacity to integrate behavioural, cognitive and affective skills to adapt flexibly to diverse social contexts and demands”.

The training content of CBT-CSCA followed the model proposed by Yager and Iarocci (2013). The seven domains of social competence were organized into four modules of training, specifically social context (social motivation and social knowledge), behavior (verbal conversational and nonverbal sending skills), emotion (emotion regulation skills and demonstrating empathic concern), and cognition (social inferencing). In each module, specific and concretized behavioral and cognitive skills are listed as targets of training. The training consisted of 15 weekly sessions (see Table 1). Each session lasted for 120 min and followed a standardized format modeling a CBT session. Typically, homework was reviewed at the beginning of each meeting, with compliance and quality recorded. It was followed by didactic teaching and role-played demonstrations on the targeted skills of each session. Newly learned skills were rehearsed by adolescents, during which they received performance feedback. The teaching was followed by a naturalistic game and snack times, during which the use of learned skills from the trainees was systematically reinforced. Before the session ended, a test on teaching materials was distributed to consolidate learning. Homework for the coming week was assigned to encourage skills generalization to natural settings.

Culturally Sensitive Social Competence Training Program for Chinese High-Functioning Adolescents with ASD, A, Table 1 Overview of the CBT-CSCA

Session	Module	Contents	Homework
1	Social context: motivation	Introduce the purpose, structure, and rules of the training program Enhance motivation in group participation	Adolescents record social encounters and the benefits of these encounters
2	Social context: knowledge	Understand hidden social rules in social contexts Learn how to detect hidden social rules in social contexts common to adolescents Introduce perspective-taking questions	Adolescents detect hidden social rules in contexts common to them and evaluate their performance in following them
3	Social context: knowledge	Understand general social rules across different social contexts Learn how to detect general social rules	Adolescents apply skills in detecting general social rules in different settings
4	Behavior: active listening	Learn active listening skills Detect signals of exiting conversations and practice their application	Adolescents apply active listening skills and signals of exiting conversations
5	Behavior: conversation	Learn how to end and maintain conversations Understand four conversation blockers	Adolescents practice skills in ending and maintaining conversations
6	Behavior: conversation	Learn how to initiate and maintain conversations Practice skills in initiate, maintain, and end conversations in different social contexts	Adolescents practice integrated skills in initiating, maintaining, and ending conversations
7	Behavior: electronic communication	Learn how to join a group conversation Learn skills in electronic communication	Adolescents practice skills in joining a group conversation and electronic communication
8	Emotion: facial recognition and expression	Understand how to recognize emotions through facial expressions Practice expressing emotions through facial expressions	Adolescents practice recognizing and expressing emotions using facial expressions with family members
9	Emotion: Gestural and tonal recognition and expression	Understand how to skills emotions through tonal and gestural expressions Practice expressing emotions through tonal and gestural expressions	Adolescents record an emotional incident and retell it with application of facial, tonal, and gestural expressions
10	Emotion: regulation	Learn skills to handle criticisms and related negative emotions	Adolescents record incidents of criticisms and how they apply the skills in handling criticisms
11	Emotion: empathy	Understand what empathy is Learn how to deliver empathic responses	Adolescents record incidents that they apply the skills taught in delivering empathic responses
12	Cognition: social inference	Learn how to make inference on others' thoughts	Adolescents record incidents that they apply skills in making inference on others' thoughts

(continued)

Culturally Sensitive Social Competence Training Program for Chinese High-Functioning Adolescents with ASD, A, Table 1 (continued)

Session	Module	Contents	Homework
13	Integration: friendship building	Understand interpersonal circle Learn how to join group activities and detect unwelcome signals	Adolescents build a friendship with one of the members of the group by phone conversations or electronic communication
14	Integration: planning group activities	Learn how to invite others to join group activities and plan for group activities	Adolescents prepare their speech to be shared at the graduation party
15	Graduation	Share learning in the program Celebrate for graduation	N/A

Regarding cultural-sensitive elements, familiar social contexts unique to local youth were first identified and subsequently included as a basis for training. These social contexts included dining out with family relatives, visiting extended family members, group project discussion in school, and visiting arcade with peers. Besides, training activities and games were designed concerning the local popular culture. For instance, a popular local game that the winner of rock-paper-scissors would become an “emperor” was modified to require players to demonstrate active listening skills in becoming the emperor. Common local board games were also prepared during the naturalistic game time in each session.

The training program was conducted by trained workers, who were registered clinical psychologists, counselors, or social workers, all with a graduate or postgraduate qualifications and substantial experience in conducting social competence training with adolescents with ASD. Workers were fully trained in the CBT-CSCA with confirmed competence. The implementation fidelity of the training was ensured through regular on-site checking regarding the established manual and bi-weekly supervision by the first author (RC).

The CBT-CSCA was validated with local assessment tools on social competence, autistic symptoms, general psychopathology, and parental stress. In a group of 25 adolescents (aged 12 to 17 years, with an FSIQ above 80), significant improvements in social competence, autistic symptoms, and general psychopathology at post-training and 3-month follow-up were reported by

the parents. The findings provided evidence support to the integrative multi-module approach of CBT-CSCA and its crucial training components. The positive results on autistic symptoms and general psychopathology in the present study support the spillover effect of social competence training on improving the related symptoms of ASD. The inclusion of emotion and cognition components in CBT-CSCA is considered to be contributive to the observed significant positive changes. The findings also support the proposition that ASD is primarily a social development disorder and addressing social deficits is a centrality approach for ASD (Chan et al. 2014).

The CBT-CSCA was guided by established theoretical propositions, appropriate cultural adaption, empirically supported training strategies, and relevant contextual contents. It also gives preliminary evidence to the validity of using such an approach in constructing culturally sensitive and effective social interventions for persons challenged by ASD. Apart from the cultural components, CBT-CSCA also adopts an integrative multi-module approach and underlines the importance of context, behavior, emotion, and cognition in social competence learning. Unlike the common practice of translating and adopting foreign-developed training program, the CBT-CSCA was locally developed, with the incorporation of culturally sensitive training contents and activities. The program was not only theoretically valid and empirically supported, but it also accommodated the unique cultural needs of Hong Kong adolescents. The CBT-CSCA also served as an exemplar of developing local

treatment programs via cultural adaptation in the mental health setting.

Future Directions

Despite availability and provision of intervention at the younger age, intervention gains do not seem to translate into adulthood. Prognosis in adulthood was often unsatisfactory (Levy and Perry 2011). Social incompetence often remained to be one of the most disabling impairments among adults with ASD, potentially contributed by the rise in complexity and salience of social relationships (Tantam 2003).

To address the continuity of social impairments, adults with ASD would need psychosocial interventions addressing their unique social challenges. Although there is social skills intervention for adults with high-functioning ASD (see Spain and Blainey 2015 for a review), studies were mostly in lack of cultural diversity, in which all were conducted in the Western countries. There was a need for effective intervention to serve the ASD population in the East. Given the demonstrated effectiveness of CBT-CSCA in adolescents, the extension in the application of CBT-CSCA on adults with ASD shall be investigated.

Definition

The understanding of autism can only be gained by further examination of autism both across and within cultures. Careful attention to observed similarities and differences will allow a better understanding of the disorder as well as better design and development of interventions that are applicable to families of all backgrounds. This entry describes research to date on how culture influences the epidemiology, diagnosis, and treatment of autism throughout the world, with a special focus on family functioning, and disparities in diagnosis and care.

Historical Background

While knowledge about autism is increasing rapidly throughout the world, there are to date few scientific studies of the characteristics, prevalence, and phenotypes of autism spectrum disorder (ASD) outside of North America and Western Europe and how culture, race, and ethnicity influence the understanding and management of ASD. Researchers have long agreed that autism occurs

in families across races and socioeconomic backgrounds and, based on the presence of autism parent organizations in more than 100 countries, there is clear evidence that a constellation of behaviors has been recognized as “autism” on every continent. Researchers are just beginning to study, however, the extent to which ASD varies both across and within cultures. While there appear to be similarities in the onset and core symptoms of ASD around the world, this remains an untested assumption. ASD experts to date are gradually learning more about how cultural differences may influence its prevalence, diagnosis, treatment, presentation, course, and family function.

Current Knowledge

Prevalence

The received view is that the prevalence of autism is consistent across races and cultures (Fombonne 2003). However, for many years, epidemiological studies were carried out primarily in North America and Western Europe. Work from outside these areas was limited, with the notable exception of Japan (e.g., Honda et al. 2005; Matsuishi et al. 1987; Sugiyama and Abe 1989). In recent years, reports of prevalence have come from Singapore (Bernard-Optiz et al. 2001), Iran (Samadi et al. 2011), China (Wong and Hui 2008), Oman (Al-Farsi et al. 2011), Venezuela (Montiel-Nava and Pena 2008), Sri Lanka (Perera et al. 2009), and Korea (Kim et al. 2011), among others. Most studies provide prevalence estimates similar to those for the USA, although Kim et al. found more than twice the prevalence of US studies in South Korea. Prevalence studies have used a wide range of methods and are therefore difficult to compare to one another. Moreover, autism epidemiologists face the difficult task of reliably defining cases based on information from teacher and parent reports, both of which can be heavily influenced by cultural attitudes about discipline and what kinds of behaviors are age appropriate. Estimates of autism may appear higher in a country with great awareness among parents, educators, and clinicians and access to services or in

which the national government mandates the use of autism as a diagnostic term. In contrast, estimates may be lower in a country with little awareness, few services, and lack of systematic surveillance through research or administrative means. In the USA, for example, school records of autism grew tremendously following the 1991–1992 school year when the U.S. Department of Education first introduced these terms to the American public school system (Newschaffer et al. 2005).

Research on the prevalence of ASD among children of immigrants dates back more than 20 years. These studies have hypothesized a range of possible explanations for what appears to be higher rates in these children, including vulnerability to intrauterine infections and vitamin deficiencies, among others (Dealberto 2011; Gillberg et al. 1987, 1991, 1995; Narayan et al. 1992). Conclusions from this work are limited by small sample sizes. While some researchers believe they do not support an association, others note that maternal birth abroad represents at least a marginal increase in risk of having a child with ASD (Gardener et al. 2009). Recent work from the UK found a significant association of risk for immigrant mothers, particularly from the Caribbean (Keen et al. 2010). Similarly, data from the 3–4-year-olds in the Somali community in the US city of Minneapolis found the prevalence of ASD to be as much as seven times higher for Somali children than for non-Somali children, although this ratio was observed to decrease dramatically over time (Minnesota Department of Public Health 2009).

Diagnostic Processes

Although researchers may use standardized assessments and criteria – at the very least, The Diagnostic Statistical Manual of Mental Disorders (DSM) and The International Classification of Diseases (ICD) – to determine whether an individual constitutes a “case” of autism, most physicians and psychologists are not integrated into a research community and are likely to rely on past training and personal clinical experience. Even with standardized criteria, considerable subjectivity and differences in clinical assessments exist

because the diagnosis depends on patient or caretaker narrative combined with behavioral observation rather than biological tests. Research in India (Daley and Sigman 2002), Pakistan (Rahbar et al. 2011), and Nigeria (Bakare et al. 2009) shows that professionals can hold different beliefs about the criteria that are important for diagnosis of autism, and many have never even heard of the disorder. In South Korea, children that American clinicians might diagnose with autism are often diagnosed with reactive attachment disorder (RAD), pejoratively referred to as “lack of love” (*aejŏng kyŏlpip*), a term that parallels the older American concept of the “refrigerator mother.”

Cross-cultural variations in diagnostic practices for autism have been found, even among communities whose scientific traditions are often assumed to be similar, such as the USA and western European countries. For example, in the USA, the American Psychiatric Association removed autism from the category of “psychosis” in 1980, but the French child psychiatric establishment, which uses its own indigenous manual of mental disorders, the *Classification Française des Troubles Mentaux de l'Enfant et de l'Adolescent* (CFTMEA), classified autism as a psychosis until 2004. French health professionals also conceptualize the etiology of autism differently from other European countries and consider the American classification of pervasive developmental disorders (PDDs) to be a product of Anglo-American culture. Since French health professionals generally view autism as a problem that lies within family social relationships and with the mother-child relationship in particular, there are only a few psychiatric or medical centers with expertise on autism as a genetic or brain disorder.

Clinicians may not make or record a particular diagnosis, and parents will not seek it, unless the diagnostic term is meaningful and in current use. For example, one report of the Navajo Indians of the American Southwest notes that autism is characterized as “perpetual childhood” (Connors and Donnellan 1995), and through the mid-1990s in India, it was not uncommon for clinicians to refer to children with autism as *paagol*, the Hindi word for madness (Daley 2004). In rural South Korea,

the catch-all “brain disorder” can be used for children with disorders including traumatic brain injury, autism, epilepsy, speech and language disorders, Down syndrome, and other clearly genetic disorders. In addition, many parents in South Korea prefer a RAD diagnosis to autism because (1) it is believed to be a temporary condition treatable by giving love and affection; (2) by blaming the mother, blame is deflected away from the larger family, including the lineage and lineage ancestors; and (3) the diagnosis makes sense in South Korea’s changing social context, which includes the recent integration of mothers into the work force, thereby altering family life and child care and justifying concern about mothers’ attachment to their young children (Grinker 2007).

It is not clear whether diagnostic tools are sensitive to cultural differences, and while many autism screening and diagnostic tools may demonstrate satisfactory properties, they should not be assumed to have applicability in a given culture without some level of validation. Items may need to be tailored to language impairment as it is defined in particular languages and cultures. For example, the Modified Checklist for Autism in Toddlers (M-CHAT) has been translated into more than 40 languages and tested in a number of countries, including China, India, Sri Lanka, Egypt, Kuwait, Jordan, Oman, Qatar, Saudi Arabia, Syria, Tunisia, and Lebanon. While used in many countries, careful validation is not always completed. In at least one location – Sri Lanka – the tool demonstrated unacceptably low specificity (Perera et al. 2009). The authors cite both a lack of cultural relevance of some items, as well as a consistent pattern in which social and communication impairments were not viewed as an abnormality by the mothers. A “symptom” such as poor eye gaze in a 2-year-old may be seen as an impairment in one society but politeness in another. Language is another example of the need to consider cultural practices and norms. For example, while a commonly reported impairment associated with autism among English speakers is pronominal reversal, it occurs rarely in languages, such as Korean and Javanese, in which pronouns are seldom used. Many East Asian languages use

honorifics to denote the status of the speakers in particular conversations and settings, so the inappropriate use of honorifics is an indicator of deficiencies in an individual’s ability to understand the pragmatics of shifting referents and social context.

Within the USA, race, ethnicity, and socioeconomic status all play a role in which children are identified as having autism. Mandell et al. (2002) found that African-American children subsequently diagnosed with autism are at least 2.5 times less likely to receive a diagnosis at their first specialty visit than a white child with autism. Work by Jarquin et al. (2011) found that non-Hispanic Black children receive only the most severe diagnosis of ASD, in contrast to non-Hispanic White children who receive diagnosis at all levels of severity. Using data collected from states on the number of children eligible for special education services under the category of autism, Morrier et al. (2010) found significant underrepresentation for Hispanic children in 95% of US states. Travers et al. (2011) were able to document that this particular finding has persisted between 1998 and 2006, while the likelihood of eligibility based on ASD varied across time for other minority groups. Educational eligibility is clearly not equivalent to diagnosis, although these findings are consistent with the recommendation by Mandell and Novak (2005) to conduct research on “the complex relationship between culture and treatment, focusing on cultural differences in the behavioral phenotype of ASD, recognition of symptoms, interpretation of symptoms, families’ decisions regarding medical and educational interventions, and interactions between families and the healthcare system” (2005, p. 114).

It must be emphasized that cultural variables, such as local conceptions of the normal and abnormal, stigma, and attitudes about disclosure, cannot be easily measured, in large part because there are so many cross-cultural differences in the norms of child rearing. The use of qualitative ethnographic methods, such as cultural consensus analyses, provides systematic data on attitudes toward health and illness that can be quantified and converted into schematic models of shared beliefs

(Romney et al. 1986). Researchers can then quantify levels of agreement among informants and identify both shared cultural categories as well as intercultural differences.

Every geographic location and community may demand different methods and types of description. An ethnographic study of help-seeking for ASD in the USA would likely focus primarily on the relationship between parents and health care providers, while the same study in Kenya would likely focus on an extended-family disease management group and how the family negotiates a plurality of coexisting medical and religious systems. In other words, although autism appears to be universal, the contexts in which it occurs are distinctive.

Treatment

The availability of providers and clinical services that are specific to ASD remains one of largest challenges in most countries in the world. Intervention programs for children with ASD have largely developed under conditions that are both culturally inconsistent and economically untenable for most low- and middle-income countries. Indeed, researchers must also be aware of the cultural fit of many interventions, especially for minority groups within the USA. One intervention approach that is well known for its adaptability in a number of different countries is treatment and education of autistic and communication-related handicapped children or TEACCH (Schopler and Mesibov 2000), a training, services, and research program that has been implemented in a wide range of countries, including Australia, Brazil, Cambodia, Denmark, Iceland, Italy, Germany, Greece, India, Israel, Japan, Kuwait, Mexico, New Zealand, the Netherlands, Republic of Ireland, South Africa, Spain, Sweden, UK, Venezuela, and Vietnam. The flexibility to create new materials and the ability to apply the general principles of the program have likely contributed to its successful adaptation.

School- or classroom-based interventions are only effective, however, if children with ASD attend school. Many children with ASD and other disabilities simply do not attend school at

all. Estimates by the United Nations Children's Fund (UNICEF) and the United Nations Educational Scientific and Cultural Organization (UNESCO) place the percentage of children with disabilities living in developing countries who receive a basic primary education to be between 1% and 5%. In these countries, school-based opportunities are limited primarily to the urban areas, and even in these situations, children with autism are typically in settings where professionals have little knowledge about effective practices specifically for children with ASD. In Ghana, for example, classrooms were described as "crowded, loud, and unpredictable" and "transitions between activities generally occurred without warning, after inconsistent durations and at varying times of the day" (Anthony 2009, p. 9), conditions which are both typical in most low- and middle-income countries and also challenging for many children with ASD.

In the absence of laws and regulations that provide services, parents of children with ASD may engage in a high level of help-seeking and may use a combination of local healers, indigenous systems of medicine, medication, and Western treatments for ASD. In China, for example (Clark and Zhou 2005), there is wide use of sensory integration therapies in addition to applied behavioral analysis (ABA). In India, families have long relied on both special education and traditional healing systems, such as the use of Ayurvedic and homeopathic medicine (Daley 2002). They now also seek treatments for their children that include hyperbaric oxygen chambers, stem-cell replacement, Defeat Autism Now (DAN) diets, auditory integrated therapy, and many others. Of course, such options are not available to most families and in most countries, regardless of whether they are effective. As is true for families throughout the world, parents in Taiwan reported a willingness to try anything that might work, from fortune tellers to vitamin supplements (Shyu et al. 2010).

Family Functioning

Just as the impact of a child with autism on the family varies widely within cultures, it also varies considerably across cultures. In many countries,

having a child with a disability of any type is made even more challenging as a result of the stigma associated with such a difference. Stigma is generally defined as a form of branding of an individual in which a community devalues his or her social identity. In Korea, for example, despite dramatic changes in autism awareness in all segments of society, autism (*chap'ae*) continues to be a highly undesirable disability, and the diagnosis is believed to be applicable primarily to children and adults with profound intellectual impairments. Other cultures provide pathways that minimize stigma. In India, the recent positive portrayal of people with ASD on television and in films, even if inaccurate, has opened dialogue about disability and has provided a point of cultural reference, and in some cases, pride (Singhal 2010). In the USA, many people who have both ASD and above-average intelligence, while facing social challenges, still find gainful employment in the fields of engineering, computers, or mathematics.

Within North America and Europe, the parenting experience of minority groups can involve additional challenges as a result of cultural differences. Kediye et al. (2009) described challenges faced by Somali parents, such as the language barrier in communicating with key professionals; a perception of racism and being judged; misguided advice from the general public who assume poor parenting; and a sense of estrangement in the absence of extended family. However, it is important to recognize the wide variability in experiences across minority groups. For example, Magaña and Smith (2006) found that Latina mothers of children with ASD had significantly better overall well-being than their non-Latina counterparts and reported striking differences in the degree to which Latina mothers held more positive beliefs about their children.

Future Directions

The understanding of autism can only gain by further examination of autism both across and within cultures. Careful attention to observed similarities and differences will help researchers and

clinicians better understand the disorder as well as better design and develop interventions that are applicable to families of all backgrounds. Some specific potential areas for future work include the following areas:

- As immigration patterns continue to shift with political changes in every corner of the globe, researchers are presented with continually changing options for investigation of *immigration and prevalence of ASD*.
- Pediatricians and primary health care workers are in need of *simple, reliable methods of identifying ASD* that do not require extensive training. More research on the *validity of diagnostic tools cross-culturally* is needed to equip these professionals with the instruments they need to accurately diagnose ASD.
- The dramatic gap in appropriate intervention options for the majority of children in the world with ASD suggests the need for researchers to work closely with professionals on the ground to *develop intervention approaches* that are cost-effective, feasible, and culturally relevant.
- Relatively little research has examined whether there are *differences in symptom expression* across cultures. *Genetic studies* are underway in many non-Western countries, which will allow much greater understanding of how genetic heterogeneity and culture interact to influence the presentation of ASD.

Curriculum

Louise Spear-Swerling
Southern Connecticut State University, New Haven, CT, USA

Definition

Broadly defined, a curriculum is the set of courses, including the specific course content and sequence of topics, taught in schools. The term *core curriculum* refers to the set of courses and content typically required of all students in a school. In K-12 education, core curriculum would usually include reading, writing, mathematics, science, and social studies, as well as the arts and physical education. Additionally, the term *curriculum* sometimes is applied within a particular domain (e.g., the reading curriculum or the math curriculum). Curricula within a particular domain include specific subtopics or component areas, with some sequencing of subtopics and skills. For instance, a reading curriculum in the primary grades (K-3) should address component areas such as phonemic awareness, phonics,

fluency, vocabulary, and comprehension; within a component area, the curriculum would address easier skills before more difficult ones. In the area of phonics, for example, children would be taught to read simple, one-syllable words before two-syllable words, and two-syllable words before complex multisyllabic words. The term *curriculum* is not synonymous with *instructional program*. A curriculum could be implemented through the use of one particular instructional program or set of programs, but it could also be implemented through instructional activities developed by teachers or schools.

Historical Background

Some countries, such as the United Kingdom, have a national curriculum which standardizes specific course content by grade. Although the United States has no national curriculum, virtually all states have their own standards for important academic domains such as mathematics or reading. These state standards provide some guidance to local school districts about what state education officials view as important content for each grade level, K-12. Professional organizations and scholarly panels (e.g., the National Early Literacy Panel, the National Math Advisory Panel) also provide guidance to educators regarding important curriculum content. Nevertheless, K-12 curricula can vary substantially from one state to the next or even within a state, across districts, meaning that curricular expectations for children at a particular grade level also can vary substantially.

Future Directions

The Common Core State Standards Initiative (www.corestandards.org), a state-led effort coordinated by the National Governors Association Center for Best Practices (NGA Center) and the Council of Chief State School Officers (CCSSO), has outlined evidence-based standards by grade level for K-12 English/language arts and mathematics. States choosing to adopt these standards would be addressing similar skills and content in their core curricula, which might lead to more

consistency across and within states in expectations for students in each grade.

²Post-Baccalaureate Certificate Program in Autism Studies, College of Health Professions, Towson University, Towson, MD, USA

Definition

Custodial grandparents of children with autism spectrum disorder (ASD) serve as head of their

household; assume primary responsibility for at least one biological, adoptive, or step-grandchild diagnosed with ASD; and may or may not have their caregiving responsibilities recognized via legal adoption, guardianship, or formal custody arrangements. Families comprised of custodial grandparents and their grandchildren are called grandfamilies, kin care, custodial, and skip-generation families.

Historical Background

Research on custodial grandparents of children with ASD was predicated by general studies of US grandparents who lived in the same household as their grandchildren. Although the Census Bureau began to gather data on grandparents who lived in the same household as their grandchildren in the 1970s, a lack of data regarding the individual characteristics of those grandchildren, coupled with multiple changes in autism's diagnostic nomenclature, has made it difficult, if not impossible, to discern the number of custodial grandparents taking care of a child with ASD.

In 1970, the US Census Bureau reported that 2.2 million grandparents lived in the same household with a grandchild, but it was not possible to determine if those grandparents served as primary caregiver for their grandchild or if they co-resided with additional members of the child's family including the child's parent or parents. Over the next few decades, increasing numbers of grandparents "lived under the same roof" as their grandchildren; by 1997 more than 3.9 million grandparents lived with a grandchild (see Hayslip and Kaminski 2005). Meanwhile, while the 1994 *Diagnostic and Statistical Manual of Mental Disorders* (DSM), 4th edition, identified childhood autism as a developmental disorder that included individual diagnoses of Asperger's disorder, PDD-NOS, autism, childhood disintegrative disorder, and Rett syndrome, the Census Bureau did not collect enough data to determine how many of those 3.9 million grandparents served as custodial, versus co-resident, grandparents, much less custodial grandparents of a child with autism (i.e., ASD).

By the turn of the century, the Census Bureau (1999) collected data that allowed for the

identification of custodial, as well as co-resident, grandparents and reported that of the 4.6 million US grandparents who co-resided with a grandchild, 1.3 million of them served as custodial grandparents. These custodial, compared to co-resident, grandparents were also more likely to be grandmothers, to live in poverty, and to not have health insurance for their grandchild (1999). When the DSM-5 (APA) introduced ASD as an umbrella diagnosis for autism in 2013, it was still not possible to obtain a population count of custodial grandparents of children with ASD via the Census Bureau, and no formal research studies of custodial grandparents of children with ASD existed in the literature. However, recognized experts in grandparenting like Hayslip began to examine the custodial grandparents of children, in general. A review of this early literature on custodial grandparents, in general, revealed five primary themes including the heterogeneity of this population, the personal costs and benefits associated with assuming this role, the use of various parenting styles, a desire for social support and connection, and a need for essential social and health services (Hayslip and Kaminski 2005).

Current Knowledge

It remains impossible to obtain an accurate count of the number of custodial grandparents of children with ASD in the USA; no governmental or private organizations gather the appropriate data to make that official determination. One can, however, estimate how many grandparents currently serve as custodial grandparents for children with ASD in the USA. The Census Bureau indicates that 2.7 million custodial grandparents in the USA currently provide care for 2.5 million grandchildren (Cancino 2016). When combined with current prevalence rates of ASD, in which 1 out of 58 US children receive a diagnosis of ASD (Autism and Developmental Disabilities Monitoring Network 2018), 43,103 of those 2.5 million children cared for by custodial grandparents could be estimated to carry an ASD diagnosis. Because additional census data indicate that custodial grandparents care for grandchildren at a ratio of 1.08 grandparents to 1 grandchild

(Cancino 2016), those 43,103 children diagnosed with ASD would be expected to be cared for by a total of more than 46,500 US custodial grandparents.

Our knowledge of the estimated, more than 46,500, custodial grandparents in the USA currently caring for children with ASD remains limited. Important reference groups for the custodial grandparents of children with ASD include the parents of children with ASD; the parents of children with other disabilities and chronic illnesses; the custodial grandparents of children, in general; and the traditional grandparents of children with ASD. A review of these reference groups will provide useful background information and points of comparison for it currently knows about custodial grandparents of children with ASD.

The parents of children with ASD serve as an essential reference group for custodial grandparents of children with ASD; the custodial grandparents of children with ASD, who assume the role of surrogate parent, can be expected to share similar experiences, challenges, and demands (Hillman and Anderson 2019). It also is essential to note that the parents of children with ASD, compared to the parents of children with other kinds of chronic illness and disabilities (e.g., hearing and vision loss, Down syndrome, cerebral palsy, intellectual disability, and diabetes), experience a variety of unique, additional stressors (see Hillman and Anderson 2019). These stressors include the challenging behavioral and communication problems typically exhibited by children with ASD like elopement, tantrums, meltdowns, insomnia, sensory sensitivity, stimming (e.g., hand flapping, headbanging), an insistence upon sameness, physical aggression, restricted and unusual interests, restricted food choices, and difficulty with verbal and non-verbal communication. Additional, unique challenges for parents of children with ASD, compared to parents of children with other chronic disorders and illnesses, include difficulties in obtaining appropriate ASD-related services, transporting their child to a variety of appointments, and obtaining daycare and respite care, social isolation, and the need to spend more time interacting with insurance companies, school personnel, and various agencies to acquire appropriate services (Cidav et al. 2012).

Among parents of children with ASD, one parent (typically the mother) often takes on the role of the personal case manager, advocates for the child with ASD, and assumes primary responsibility for transportation to ASD-related appointments, management of ASD-related problem behaviors, and before-and-after-school, evening, weekend, holiday, and summer childcare. Because many of these primary caregivers often lose the ability to work a typical workweek outside of the home, mothers of children with ASD earn 56% less than mothers of children in general and 35% less than mothers of children diagnosed with other chronic illnesses and disorders (Zuleyha et al. 2012). This decrease in household income only adds to the increased financial burden of parents of children with ASD who typically need to cover the cost of ASD-related therapies, medical care, specialized school instruction, summer programs, and day and respite care (Cidav et al. 2012).

Parents of children with ASD face additional stressors in their relationships with spouses and partners and often express fear regarding their child's future, particularly after their own deaths. These parents have expressed, "Who will love and care for my child with ASD after I pass away? Will my child be able to live independently, or will they be placed in a group home or institution? Who will make sure that they are cared for and not emotionally, physically or financially abused?" This combination of demands in caregiving, challenges with ASD-related problem behaviors and lost wages can lead parents of children with ASD to experience social isolation, anxiety, and depression (Dyches et al. 2016). It can be expected that the custodial grandparents of children with ASD would have a similar experience.

Another essential reference group for custodial grandparents of children with ASD is that of custodial grandparents of children, in general. In terms of providing long-term social benefits, custodial grandparents of all children prevent those children from entering an already typically underfunded, overworked, and insufficient foster care system (Hayslip et al. 2019). Despite providing this essential social service, however, research suggests that custodial grandparents of children,

overall, represent a disproportionate number of minority group members and are subject to a variety of challenges and stressors. For example, custodial grandparents often assume their role in response to a crisis related to a parent's divorce, death, incarceration, mental or physical illness, military deployment, substance abuse (e.g., increasingly frequent opioid use), or participation in child abuse and neglect (Hayslip et al. 2019). Custodial grandparents of children, overall, are also more likely to be African American, Latino, and grandmothers (Hayslip et al. 2019) living on a fixed income with a chronic illness (or mental or physical disability) and with less formal education (Muthiah et al. 2018) when compared to both partnered and single parents of children, in general.

Custodial grandparents of children, in general, also report feeling guilt, shame, insecurity, sadness, and frustration (Muthiah et al. 2018) within the context of their role, as well as anxiety and depression (Hayslip et al. 2019). This negative effect may arise from stressors including the crisis that led up to their caregiving, ambiguity about their role as grandparent versus parent, uncertainty about their parenting skills, a loss of independence and privacy, increased conflict with their partner or spouse, and increased spending for their grandchild's food, clothing, and other basic needs, challenges in finding same-age custodial peers, and a grandchild's problem behavior. However, custodial grandparents of children, in general (Hayslip et al. 2019), also appear to demonstrate resilience, and they have responded well to small group intervention. In response to feelings of social isolation, custodial grandparents, in general, who participated in both formal and informal support groups (Hayslip et al. 2019) experienced lower levels of stress and depression.

Understanding the experience of traditional, versus custodial, grandparents of children with ASD offers another point of comparison. Based upon the largest national survey of traditional grandparents of children with ASD to date, more than 1800 grandparents of children with ASD who responded provided both emotional and instrumental support to the parents of their grandchildren with ASD (Hillman et al. 2016). Specifically, traditional grandparents of children

with ASD reported that they often provide childcare so that a parent can work outside the home, respite care, transportation to and from ASD-related appointments, advocacy and assistance in dealing with school personnel and insurance agencies, and significant financial support well beyond paying for essentials like food and clothing. To provide this financial support, many of these grandparents made significant personal sacrifices and put off their retirement, went back to work after they had been retired or partially retired, raided their retirement and other savings accounts, and even moved in with, or closer to, their grandchild with ASD. Findings also indicated that traditional grandmothers of children with ASD were more likely to provide emotional and instrumental support, while traditional grandfathers of children with ASD were more likely to provide financial support.

Additional, qualitative analyses of the responses of more than 1800 traditional grandparents of a child with ASD regarding their first-person experience (Hillman et al. 2017) revealed that these grandparents experienced joys as well as challenges in their relationship with their grandchild with ASD. Specifically, these traditional grandparents enjoyed having a special relationship with their grandchild, which often transcended their grandchild's inability to communicate via spoken language. However, this special relationship was often tempered by ASD-related behavior problems like tantrums, meltdowns, elopement, aggressive behavior, and the desire to communicate verbally with a non-verbal grandchild. A central finding was that despite these challenges, these traditional grandparents of children with ASD typically reported that they found solace and joy in celebrating every bit of progress that their grandchild made, no matter how small (Hillman et al. 2017). Additional themes identified by these traditional grandparents of children with ASD included a newly discovered ability to love their grandchild unconditionally and the value they typically found by engaging in ASD-related advocacy. Additional qualitative findings (Prendeville and Kinsella 2019) indicate that although traditional grandparents of children with ASD also experience regret losing some of their personal freedom

when they commit to helping with their grandchild's daily care, they knew they provided an invaluable service. Unlike the parents of children with ASD, however, the traditional grandparents of children with ASD (Hillman et al. 2017; Prendeville and Kinsella 2019) appear to experience a "double dose" of worry and fear in which they express significant fear and anxiety about both the future of their grandchild with ASD and their grandchild's parents, which increased when they thought about becoming too sick or frail to help or passing away.

Although limited, the research available regarding custodial grandparents of children with ASD is drawn primarily from qualitative studies (e.g., Hillman and Anderson 2019). Findings suggest that, like traditional grandparents of children with ASD, the custodial grandparents of a child with ASD experience both challenges and joys in their dual, and often conflicting, role as grandparent and surrogate parent. Specifically, custodial grandparents of children with ASD reported that problematic issues with their grandchildren's parents (i.e., their adult child and/or their adult child's partner) serve as one of their greatest challenges. Challenges include dealing with the original crisis that led to them assuming their role as primary caregiver, obtaining legal custody of their grandchild with ASD, and conflicts that often arose during visitation with the child's parent or parents. The custodial grandparents of children with ASD also reported that caregiver burden, including 24/7 demands, challenging ASD-related problem behaviors like tantrums and eloping, insufficient ASD-related services, increasing financial demands, social isolation, and related fears for their grandchild's future, represented another significant challenge.

However, custodial grandparents of children with ASD also report that they experience joy and positivity in their role (e.g., Hillman and Anderson 2019). Sources of joy include learning to love unconditionally; to celebrate each time their grandchild with ASD made progress, no matter how small or incremental; to focus on the positive; and to draw upon their religious and moral beliefs (e.g., my grandchild is a gift from God, and taking care of him is the right thing to do) during difficult times. Custodial grandparents

of children with ASD also report developing wisdom as a function of their role, including the acknowledgment that it really does "take a village" including friends, teachers, and various professionals to raise a child with ASD and the importance of advocacy and education about ASD for their both own grandchild and for society as a whole.

In sum, research suggests that custodial grandparents of children with ASD face significant stressors and burden, above and beyond those of parents of children with ASD, caregivers of children with other chronic illnesses and disabilities, custodial grandparents of children overall, and traditional grandparents of children with ASD. The custodial grandparents of children with ASD often face additional struggles with living on a fixed or limited income, feeling conflicted about their dual role as parent and grandparent, having few peers, having their own health problems, experiencing a "double dose" of worry for both their grandchild with ASD and their grandchild's parents, and not having their own grandparents to help them with finances or respite care.

Because custodial grandparents of children with ASD have identified social isolation, needing help with ASD-related problem behaviors, around-the-clock demands for caregiving, and financial strain as primary stressors (Hillman and Anderson 2019), the use of online resources available 24-7 from the caregiver's home or portable cell phone (as long as they have Internet access) appears appropriate. Exemplars of potential online resources for custodial grandparents of children with ASD are provided in Table 1. It is notable that *Autism Speaks*, a national nonprofit organization designed to offer advocacy, research, and support for families, was founded in 2005 by two traditional grandparents of a child with ASD who described feeling lost, without adequate resources, when they first learned about their grandson's diagnosis.

Future Directions

Significant gaps in the literature regarding custodial grandparents of children with ASD will be identified here in the hope that they could be

addressed with future research, practice, and policy changes. For example, it would be helpful to obtain an accurate count of the custodial grandparents of children with ASD in the USA and around the world, including their demographic characteristics. Because most research regarding the custodial grandparents of children with ASD available has been conducted with convenience samples, snowball sampling, and primarily US, White, well-educated custodial grandparents, research derived from nationally representative samples would be ideal. Consistent with calls to acknowledge the heterogeneity of custodial grandparents of children, in general (Hayslip et al. 2019), it also remains essential to acknowledge the heterogeneity of custodial grandparents of children with ASD. Additional research can focus upon the experience and needs of custodial grandparents of children with ASD from various understudied and likely underserved groups including immigrants, LGBT adults, and African American, Alaskan Native, American Indian, Asian, Latino, Middle Eastern, and Pacific Islander adults.

Longitudinal studies of custodial grandparents of children with ASD are needed, and both quantitative and qualitative approaches to research should be valued. Consistent with current research on custodial grandparents (Hayslip et al. 2019) of children with ASD (Hillman and Anderson 2019),

future investigations should continue to examine and highlight custodial grandparents' resilience, wisdom, and other personal strengths, as well as their significant challenges. Future research should also investigate the extent to which custodial grandparents of children with ASD might use alcohol and other substances for coping, be physically abused or injured by their grandchild with ASD, and engage in child abuse, themselves. Because societal attitudes toward grandparents who serve as primary caregiver for their grandchildren have traditionally been negative (see Hayslip et al. 2019), it would be helpful to examine the attitudes maintained among case managers, teachers and other school personnel, judges and attorneys, daycare providers, and other individuals who might work with custodial grandparents of children with ASD. It also would be helpful to examine the extent to which custodial grandparents, versus parents, of a child with ASD approach that child's transition to adulthood including their pursuit of job skills, higher education, and options for group and independent living outside the family home.

In terms of policy and practice, a variety of recommendations can be offered to help address the needs of custodial grandparents of children with ASD (e.g., Hillman et al. 2019). Because these grandparents have identified problems with establishing legal custody of their

grandchild with ASD, as well as managing parental contact and behavior during visitation, legal advocates and care providers can offer education and assistance in relation to legal custody, guardianship, visitation rights, permissive visitation, and supervised visitation, which can vary significantly by state. Individual states can sponsor and promote kinship navigators, professionals trained specifically to connect custodial grandparents with state and local ASD- and custody-related resources including legal advocates in family and tax law. For example, many custodial grandparents of children with ASD may not know that they qualify for kinship guardianship payments, foster care payments, or state-supported child health insurance, much less how to apply for those benefits. Because custodial grandparents have expressed significant fears about who will take care of their grandchild after their death (Hillman et al. 2019), these grandparents can be directed to local, state, and national resources that assist in long-term care planning; the creation of a special needs trust and various custodial accounts can help ensure the quality of a child's life with ASD long after a custodial grandparent passes away.

Intergenerational programming for custodial grandparents and their grandchild with ASD could also be offered by local Area Agencies on Aging (e.g., senior centers) and Title VI Native American aging programs, perhaps in conjunction with professionals and student trainees from local colleges and universities. Such intergenerational programming could introduce these custodial grandparents to everything from case management services, legal advocacy for custody and estate planning, the National Family Caregivers Support Program, management of ASD-related problem behaviors, nutrition and feeding services, financial support (e.g., potential kinship care grants, Supplemental Security Income), and in-person and online peer support groups, to state supported respite care and transportation services when available. Ideally, such intergenerational programs would feature simultaneous programming for the grandparents' children with ASD including childcare, social skills training, music and art therapy, and other activities

and services. Addressing the challenges faced by custodial grandparents of children with ASD, while supporting their resilience and benefitting from their wisdom, appears essential.

Daily Living Skills

Aaron Stabel
The M.I.N.D. Institute, University of California
Davis Medical Center, Sacramento, CA, USA

Synonyms

Activities of daily living; Daily self-care activities; Home living skills; Self-care; Self-help

Definition

The term “daily living skills” refers to a wide range of personal self-care activities across home, school, work, and community settings. Most daily living skills, like food preparation and personal hygiene, need to be performed on a regular basis to maintain a reasonable level of health and safety. Adaptive functioning, or an individual’s ability to care for self and function independently, is a primary consideration

when supporting individuals with autism and other disabilities. Daily living skill activities include:

- Personal hygiene and grooming
- Dressing and undressing
- Meal preparation and feeding
- Mobility and transfer
- Toileting
- Housekeeping
- Laundry
- Home safety
- Health and medication management
- Leisure time and recreation

Children’s abilities to care for themselves have been found to correlate with intellectual functioning and may be a strong predictor of future independence (Carter et al. 1996). Individuals who cannot independently carry out these necessary self-help routines are at greater risk for long-term institutionalization, require more intensive living supports, and are less likely to be employed (Wehman and Targett, 2004). Assessing adaptive functioning is required when measuring intelligence, diagnosing intellectual disability, and determining appropriate treatment goals (Goodlin-Jones and Solomon 2003). The most widely used instrument to assess adaptive behavior functioning is the Vineland Adaptive Behavior

Scales (Sparrow et al. 1984). Selecting skills to teach should focus on the priority tasks required for independent domestic and community living (Wehman and Targett 2004; National Research Council 2001). Daily living skills are usually taught using strategies from applied behavior analysis, specifically task analysis, shaping, chaining, and positive reinforcement. Teaching individuals with autism to generalize learned tasks across settings, people, and materials remains an important aspect of intervention planning when teaching daily living skills.

Synonyms

[Activity schedules](#); [Daily activities](#); [Routine events](#); [Schedules](#); [Visual schedule](#)

Definition

Daily routine is a schedule, custom, or habit that is known to occur similarly on a daily frequency. Daily routines are often preferred by children and adults diagnosed with autism in order to structure their day and provide predictability. Daily routines can be inherently known by the individual without support or review by an outside person, or are scheduled out by another and presented verbally or visually. Visual schedules are often used to act as an aid in conveying the day's event and are often presented pictorially (as with picture icons) or in written form (as in a checklist). Consistent use of daily routines often helps reduce problematic behavior due to issues with transition from activity to activity. Daily routines can be expanded to teach and/or guide most events that occur daily on a large scale (i.e., activities to occur from morning to night) or for specific events (e.g., hand washing, putting away laundry).

Definition

D-amphetamine, or dextroamphetamine, is a psychostimulant primarily used for the treatment of ADHD and narcolepsy in children and adults. The drugs work by increasing the release of norepinephrine, serotonin, and dopamine from their storage sites within presynaptic nerve terminals while simultaneously also competing for reuptake by their respective transporters, thus preventing the neurotransmitters from being reuptaken effectively. This neurotransmitter release is facilitated by the activation of a membrane transport system that brings in extracellular amphetamine in exchange for pumping out the above neurotransmitters. D-amphetamine may also be a serotonin receptor direct agonist. While there is little to no substantial evidence for the effectiveness of D-amphetamine in treating ASD, use of the drug in ASD patients is high due to the high comorbidity of the disorder with ADHD. Side effects of this drug may include irregular heartbeat, headache, dizziness, weight loss, dry mouth, and others.

Definition

D-cycloserine is a partial glycine_B site agonist that binds to the strychnine-insensitive glycine binding site on the NMDA receptor, agonizing the NMDA receptor, a glutamate receptor subtype. The NMDA receptor functions in synaptic plasticity. Alterations in synaptic plasticity are believed to be at the crux of ASD pathogenesis. D-cycloserine has been shown to partially reverse social deficits in mouse models of autism. Similar benefits have been shown in human subjects as well, but further validation is still required. Because of its actions on the NMDA receptor, D-cycloserine is heavily studied in processes of fear conditioning and extinction as well as schizophrenia. In many of these studies, it is used in conjunction with behavioral therapy to allow greater control over any ensuing alterations in synaptic plasticity. Currently, D-cycloserine is only approved for the treatment of tuberculosis. Side effects include headache, drowsiness, dizziness, or shaking.

Deaf-Blind

Jennifer McCullagh and Deborah Weiss
Department of Communication Disorders,
Southern Connecticut State University,
New Haven, CT, USA

Synonyms

[Sensory impairment](#)

Short Description or Definition

Deaf-blind individuals have varying degrees of a combination of both hearing and visual impairments. In the United States, the legal definition of blindness is 20/200 in the better eye. An individual with a threshold exceeding 90 dB HL is considered to be deaf. Individuals who are deaf-blind have communication as well as mobility deficits. This dual sensory impairment results in the inability to use one sensory modality to compensate for the other. Services required for individuals who are deaf-blind are different than those required for individuals who are either deaf or blind. Communication and language development are the primary deficits in individuals with deaf-blindness; however, development of social-affective, cognitive, and motor skills is also affected. Individuals with deaf-blindness also exhibit stereotyped behaviors, similar to those seen in children with autism spectrum disorders.

Categorization

Deaf-blindness may be congenital or acquired resulting in a heterogeneous population. It is important to differentiate between these two

groups; those with congenital deaf-blindness have additional handicaps and typically require a substantially greater amount of rehabilitation, including programs that are individually tailored (Rönnerberg and Borg 2000).

Epidemiology

It is estimated that approximately 10,000 children (ages birth to 22 years) in the United States are classified as deaf-blind (Rönnerberg and Borg 2000; The National Consortium on Deaf-Blindness [NCDB] 2008). The adult deaf-blind population numbers are estimated at 35–40,000 individuals (Watson and Taff-Watson 1993).

Congenital deaf-blindness may be caused by hereditary or chromosomal syndromes and disorders, prenatal or congenital complications, complications of prematurity, and undiagnosed causes. Some common hereditary or chromosomal causes are CHARGE syndrome, Usher syndrome, and Down syndrome. Cytomegalovirus (CMV) and microcephaly are some prenatal or congenital complications that may lead to deaf-blindness. In the past, maternal rubella was the leading cause of deaf-blindness. The majority of cases of deaf-blindness are acquired; a variety of causes are responsible such as meningitis, inflicted brain damage, and aging of the sensory organs (Rönnerberg and Borg 2000).

There have been very few reports on the combined disorders of autism and deaf-blindness. The prevalence of deaf-blind individuals with autism is unknown, although it is estimated to be small. Further, because etiological factors and symptoms such as impaired social interaction and communication impairment are associated with both disorders, it is challenging to differentially diagnose between the two.

Natural History, Prognostic Factors, and Outcomes

The history of service for the population of individuals with deaf-blindness is sharply divided between the pre- and post-rubella epidemic of

1964–1965. The first citations of education with this population appeared in the mid-1800s with Laura Bridgman described as the first deaf-blind individual to learn language at the Perkins School for the Blind. Helen Keller was an even more recognized and influential figure in the success of educating deaf-blind individuals. However, even through the 1960s, limited education was available for this population, and individuals were often placed in residential schools or asylums. Congressional legislation, approved in the 1970s and beyond, which mandated education for children with disabilities, had a significant effect in advancing the education of this population (NCDB 2012).

Clinical Expression and Pathophysiology

This severe sensory deficit results in communication disorders and subsequent handicaps in education, social and cultural development, and the acquisition of information. The tactile sense is commonly utilized by these individuals for communication as well as for feelings of security and control. Other methods of compensation include use of the cutaneous senses and vibration for sound localization. Few studies have explored the psychosocial aspects of being deaf-blind and those that do typically focus on adaptation. Depression in adolescents and psychosis has been reported (Rönnerberg et al. 2002).

Evaluation and Differential Diagnosis

The evaluation process for deaf-blindness is focused on determining the extent to which the auditory and visual systems are impaired. Since the characteristics of deaf-blindness are similar to those of autism spectrum disorders, determining if comorbid autism spectrum disorders exist can be challenging. These individuals are also typically difficult to test; therefore, identification is further complicated and standardized tests are nonexistent (Vernon 2010). There tends to be an

overdiagnosis of autism in individuals with deaf-blindness leading to unsuitable intervention (Hoevenaars-van den Boom et al. 2009). These authors studied 10 individuals with deaf-blindness and intellectual disability in order to determine if they could differentiate which of these individuals also had autism (which had been previously diagnosed). They utilized an instrument that they had developed specifically for this purpose. Results indicated the presence of a significantly greater number of impaired behaviors among the individuals with autism in reciprocity of social interaction, quality of initiatives to contact, and use of adequate communicative signals and functions. The authors concluded that their instrument has promise in terms of its utilization in identifying individuals with autism within the deaf-blind population. Operant conditioning techniques have also been used successfully in the assessment of this population (Rönnerberg and Borg 2000).

Treatment

Treatment for deaf-blindness is typically focused on improving the communication, self-help skills, and mobility of the individual. Since great variability exists from individual to individual, it is imperative to establish the degree to which either the auditory system, visual system, or both can be utilized to enhance communication. The predominant therapeutic model is behavior modification (Rönnerberg and Borg 2000). It is recommended that the curriculum addresses five main areas: (1) communication skills, (2) cognitive development, (3) social and emotional development, (4) motor and self-care skills, and (5) sensory development (Murdoch 1986).

Research conducted on communicative and linguistic treatment primarily focuses on the “Tadoma” method in which the Tadoma user places his/her hand on the speaker’s face in a proscribed position. Through the use of perceptual cues, skilled Tadoma users are able to achieve a relatively high level of comprehension

of spoken speech. Intelligibility of their speech production is 60–70%; however, the rate of speech is slower by about 50%. Other methods of communication include the T-code, sign language, and textured symbols (Rönnberg and Borg 2000).

Deafness

Jennifer McCullagh
Department of Communication Disorders,
Southern Connecticut State University, New
Haven, CT, USA

Synonyms

Profound hearing impairment

Short Description or Definition

“Deafness” is a term that has varying definitions but is characterized by severe-to-profound deficits in the ability to hear. Deaf with a capital “d” is a term used to describe individuals with severe-to-profound hearing loss resulting in little to no usable hearing, even with the use of amplification devices (i.e., hearing aids, assistive listening devices, etc.). Furthermore, individuals who are Deaf belong to the Deaf culture which uses American Sign Language (ASL) as their primary mode of communication. Deaf with a lowercase “d” refers to individuals with severe-to-profound hearing loss who use amplification devices and use oral communication as their primary mode of communication.

Categorization

Degrees of Hearing Impairment in dB HL

Normal	–10 to +15
Minimal	16–25
Mild	26–40
Moderate	41–55

(continued)

Moderately severe	56–70
Severe	71–90
Profound	91+

Epidemiology

According to the National Institute of Deafness and Other Communication Disorders (NIDCD 2010), approximately 2–3 in every 1,000 children born in the United States are born with deafness or some degree of hearing impairment. Hearing loss occurs in approximately 18% of 45- to 64-year-olds, 30% of 65- to 74-year-olds, and 47% of 75-year-olds and older. More systematic research needs to be done regarding the incidence and prevalence of deafness in the population with autism.

Natural History, Prognostic Factors, and Outcomes

Individuals with severe-to-profound hearing loss are not able to hear speech sounds and most environmental sounds without amplification. If individuals with this degree of hearing loss are not treated in the first year of life, severe speech and language delays may occur. Furthermore, learning and attention disorders may often arise. Individuals with severe-to-profound hearing impairment likely need hearing aids or cochlear implants, speech and auditory training/therapy, and special education services.

Prior to the onset of the Early Detection and Intervention (EDHI) program in the late 1980s/early 1990s, children with hearing impairment were not typically diagnosed until age 2 or 3 years when speech and language delays were apparent. Since the beginning of the EDHI program, children with hearing impairment are being identified and treated earlier which is important for speech and language development (either spoken language or American Sign Language (ASL)). Early detection and intervention are critical because a sensitive period exists for speech and language

development. The first few years of life is when the foundation for speech and language is established, and if this period is missed due to an unidentified severe-to-profound hearing loss, the child will not acquire speech and/or language. The development of oral speech and language is possible with appropriate amplification or cochlear implantation in conjunction with speech and language therapy.

In postlingually deafened adults, appropriate amplification is critical to their ability to communicate with spoken language. In order to perceive what is being said, as well as monitor what their own speech, these individuals need to be fit with hearing aids, and/or assistive listening devices, or with cochlear implants.

Clinical Expression and Pathophysiology

Deafness occurs as a result of a sensorineural or mixed (conductive and sensorineural) hearing loss. Conductive hearing losses are those that occur due to pathology in the outer or middle ear. Conductive hearing losses alone only result in at most; moderate hearing losses, however, in conjunction with sensorineural hearing losses can result in severe-to-profound hearing loss. Sensorineural hearing losses occur as a result of pathology (typically hair cell loss) in the cochlea or auditory nerve fibers.

Deafness can be either congenital or acquired. Congenital deafness can be the result of genetic factors, maternal illness, and/or infection. Some examples of syndromes associated with hearing impairment are CHARGE syndrome, Usher syndrome, and Waardenburg’s syndrome. Examples of maternal illness and/or infection include rubella, cytomegalovirus (CMV), diabetes, hypoxia, syphilis, and toxemia. Acquired deafness may be the result of ototoxic medications, infection, meningitis, and encephalitis, or the cause may be unknown. Depending on the cause of the hearing loss, the impairment may, or may not, be progressive in nature. Once hearing impairment is established, annual hearing evaluations are generally recommended.

Evaluation and Differential Diagnosis

The goal of hearing evaluations is to assess the outer, middle, and inner ears. The audiologist will first perform otoscopy to determine if the outer ear (pinna and external auditory meatus) and tympanic membrane have normal appearances. Then tympanometry is completed to determine the status of the middle ear. Finally, behavioral and/or electrophysiologic testing is completed to determine hearing sensitivity at the frequencies important for speech. In behavioral testing, the goal is to complete a pure-tone audiogram which is a graphical depiction of the hearing thresholds of the octave frequencies from 250 to 8,000 Hz. Speech reception threshold and word recognition testing are also done to determine threshold to speech stimuli as well as how accurately words are perceived.

The type of hearing evaluation one undergoes depends on a number of factors, including age and ability to respond to the tonal and speech stimuli. Evaluation methods can be either behavioral or electrophysiologic. Behavioral tests require the listener to respond in some way to the tonal or speech stimuli (i.e., raise hand, turn head, repeat back words, etc.). Some examples of behavioral test procedures are behavioral observation audiometry (BOA), visual reinforcement audiometry (VRA), conditioned play audiometry, and standard audiometry. Behavioral observation audiometry occurs when the audiologist plays tonal and speech stimuli through the sound field or headphones and then watches for a response from the individual. This response might be the cessation of crying or cooing, eyes widening, or turning the head. Visual reinforcement audiometry occurs when lighted puppets positioned in boxes directly above the left and right speakers in the booth are illuminated when the stimulus is presented. This is done repeatedly until the individual is trained to look in the direction of the stimulus. During the actual testing, the stimuli are presented and the light is turned on only after the individual turns and looks toward the light. In conditioned play audiometry, hearing thresholds are obtained by using toys such as blocks. For example, the individual is trained to drop a block in a bucket every

time they perceive the beeping sound. Finally, hearing thresholds using standard audiologic procedures are obtained by having the individual raise their hand or push a button every time they perceive the tonal stimuli.

Physiologic tests, like the otoacoustic emissions (OAEs) and auditory brainstem response (ABR), do not require a behavioral response from the listener and are thus commonly used in newborn hearing screenings, infant hearing tests, as well as hearing tests on individuals who are unwilling, or unable, to respond to behavioral tests. Otoacoustic emissions are generated by the hair cells in the cochlea, so if the hair cells are absent or not functioning properly, the otoacoustic emissions will be absent or reduced. Otoacoustic emissions are often used along with ABR in populations, such as those with autism, that cannot participate in behavioral testing, to differentially diagnose cochlear hearing loss from neural hearing loss.

Treatment

In Deaf populations, no “treatment” is sought since deafness is not considered a problem. Individuals who are Deaf are taught American Sign Language (ASL) and become immersed in Deaf culture. These individuals use manual communication to interact in society.

Individuals who are deaf will often use hearing aids and/or assistive listening devices. With the advancement in technology, individuals who do have a severe-to-profound hearing loss and who do not receive benefit from amplification may get cochlear implants. Children as young as 12 months can receive cochlear implant surgery. Either method (hearing aids or cochlear implantation) must be combined with speech and language therapy in order to train the system to listen as well as produce intelligible speech.

Prognosis, evaluation methods, and treatment of individuals with autism and deafness are contingent upon a number of factors. Some of these factors include the severity of autism, etiology of the hearing loss, comorbid disorders, mode of communication, and candidacy for hearing aids

and/or cochlear implants. Ultimately, a collaborative approach should be taken when treating individuals with autism and deafness.

Deborah Fein

Diana L. Robins
AJ Autism Drexel Institute, Drexel University,
Philadelphia, PA, USA

Name and Degrees

Deborah Fein, Ph.D.
University of Connecticut
Department of Psychology, U-20
Storrs, CT, USA

Major Appointments (Institution, Location, Dates)

University of Connecticut, Storrs, CT, 1988 – current
Boston University School of Medicine, Boston, MA, 1979–2000

Major Honors and Awards

University of Connecticut Board of Trustees Distinguished Professor, 2003–
Distinguished Contribution to the Science of Psychology award, Connecticut Psychological Association, 2012
Edith Kaplan Award for Outstanding Contributions to Neuropsychology, 2012

Landmark Clinical, Scientific, and Professional Contributions

Deborah Fein has published more than 150 articles and chapters on autism spectrum disorder (ASD) since the late 1970s. Her major contributions span a number of areas, including characterizing children who show optimal outcomes after diagnosis and treatment for autism, screening to promote early detection of autism, developing theoretical models of autism, and writing seminal papers on topics such as the role of oxytocin in autism. Dr. Fein's elucidation of the primacy of social deficits in autism, described in a 1986 paper in the *Journal of the American Academy of Child Psychiatry*, as well as her theories on the neuropsychological underpinnings of autism, seen in her 1996 paper in *Psychological Review*, and her edited volume, *The Neuropsychology of Autism*, as well as her recent honor as the Birch Memorial Lecture speaker at the 2015 annual meeting of the International Neuropsychological Society, have disseminated her work to a broad audience. Her contributions to early screening, as a co-author of the Modified Checklist for Autism in Toddlers (M-CHAT), and the M-CHAT, Revised, with Follow-Up (M-CHAT-R/F) significantly impacted the early detection of autism. Her subsequent work examining the minority of children with a clearly documented history of autism, but no current symptoms, was ground breaking in its characterization of children who achieve this "optimal outcome" and no longer demonstrating deficits associated with their history of autism. Additionally, her work reaches beyond the

professional and academic audiences that access scientific journals, in her publication of a book for educators on adapting classroom strategies for children with autism, and her newest book offering parents activities to do at home with very young children at risk or diagnosed with autism. She is currently developing a website that will be available for free to parents, to teach them principles of behavioral teaching and stimulating attachment.

Short Biography

Dr. Deborah Fein, born on March 21, 1947, is a neuropsychologist who has focused much of her career studying autism. Her theoretical and empirical work in autism was heavily influenced by her training at the Boston Veteran's Affairs Hospital, under the mentorship of Dr. Edith Kaplan (with whom she published several versions of the Wechsler tests as a process instrument), and by a postdoctoral fellowship at BU School of Medicine with Dr. Al Mirsky. In addition to her scientific contributions, Dr. Fein has trained and mentored more than 50 trainees in autism and neuropsychology, many of whom now hold faculty positions in academic or medical institutions, facilitating her tremendous influence on the field. Dr. Fein lives in Western Massachusetts with her husband, and they have two daughters.

Declarative Memory

Naomi Schneider

College of Education and Human Ecology, The
Ohio State University, Columbus, OH, USA

Synonyms

[Explicit memory](#)

Definition

Declarative memory is a type of long-term memory and is memory for facts, data, words, etc. Declarative memory can be divided into three categories: episodic, semantic, and lexical. Episodic memory includes memory for personal events or experiences. Episodic memory is primarily learned consciously and is linked to a certain time and place. Examples include specific events such as walking to the store or cooking dinner. Semantic memory refers to general knowledge or facts, independent of experience. Examples include facts about historical events or types of cars. Lexical memory is the knowledge for words. It has been observed that some individuals with autism have enhanced semantic and lexical memory abilities.

Decoding Skills

Diana B. Newman

Communication Disorders Department, Southern
Connecticut State University, New Haven, CT,
USA

Synonyms

[Word recognition](#)

Definition

Decoding refers to the word recognition processes in which written words or print are transformed into spoken words. This process is commonly referred to as “sounding out words.” Proficient decoding requires rapid letter recognition, knowledge of sound-letter correspondences, phonemic awareness, and word attack skills (i.e., analysis/segmenting and synthesis/blending of the letter-sound correspondences). Accurate and fluent decoding allows for comprehension of words both in isolation and in context.

Many individuals with autism spectrum disorders (ASD) are able to mentally represent at least some single word meanings; that is, read words in isolation and understand their meanings. Some individuals with ASD spontaneously read words with excellent proficiency at an unexpectedly early age (referred to as hyperlexia); however, it is the ability to read beyond decoding individual words (i.e., reading in context) that presents greater difficulty for individuals with ASD.

Deep Pressure Proprioception Touch Technique

Winifred Schultz-Krohn
Department of Occupational Therapy, San José
State University, San José, CA, USA

Synonyms

Wilbarger Protocol

Deep pressure proprioceptive touch technique (DPPT): Previously known as the Wilbarger Protocol, DPPT was developed by two occupational therapists, Patricia and Julia Wilbarger, to address sensory defensiveness. This technique requires specific training and includes three parts where first a client's arms, back, and legs are brushed firmly with a soft-bristled brush similar to a surgical brush. Then joint compressions are applied at specified joints throughout the body, and finally a sensory diet is prescribed to address sensory defensiveness. This technique has been effectively used to reduce sensory defensiveness and has been linked to bringing salivary cortisol levels closer to normal values in children with sensory processing deficits. The cortisol levels have been used as a measure of stress in children, and with the use of the DPPT, the levels of cortisol approached a normal level. The recommended frequency for this technique

is every 2 h during waking hours for 2 weeks to see diminished sensory defensive behaviors. A pilot investigation using the DPPT was successful in reducing self-injurious behaviors in women with depression and a history of self-injurious behaviors. A follow-up 9 months after providing DPPT found women reported a decrease in self-harming behaviors.

Deficits in Attention, Motor Control, and Perception

Fred R. Volkmar
Child Study Center, Irving B. Harris Professor of
Child Psychiatry, Pediatrics and Psychology, Yale
Child Study Center, School of Medicine, Yale
University, New Haven, CT, USA

Synonyms

DAMP; DAMP syndrome

Definition

DAMP syndrome is a diagnostic concept developed by Gillberg and colleagues in Sweden and used more frequently in Scandinavia. The term refers to a disorder in which aspects of attention-deficit disorder and motor coordination difficulties are present. A close link to PDD-NOS/autism spectrum disorder has been suggested (Gillberg et al. 1993; Kadesjoe and Gillberg 1999). One complexity in this regard is the potential for attentional difficulties to lead to problems with peers and social interaction; this is particularly the case if some degree of language difficulty is involved (Towbin 2005). Issues of diagnosis can also be complex in children with significant intellectual disability, attentional, and motor problems, although it has been suggested that the DAMP concept be restricted to cases where the individual has an IQ no lower than the mild-moderate range of disability. Although the topic has not been the focus of widespread research, the issue of associations between autism spectrum disorder and attentional problems is one of the great interests for both research and clinical purposes (Davis and Kollins 2012).

Definition: Metaphor

Laura Foran Lewis
College of Nursing and Health Sciences,
University of Vermont, Burlington, VT, USA

Synonyms

[Figurative language](#)

Definition

A type of figurative language in which objects or actions are compared in a way that is implied but not literal, such as “She has a heart of gold,” or where one thing is considered as representative of the other as in symbolism (Glucksberg 2001). Typically developing children usually begin to understand and produce simple metaphors as early as 2 years of age and progress to more advanced comparisons with age, showing significant improvements around age 4–5 years and continuing to develop these skills into adulthood (Stites and Ozcaliskan 2012). Children on the autism spectrum with autism demonstrate poorer comprehension of figurative language than their typically developing peers (Kalandadze et al. 2019).

Two theories are proposed to explain difficulties in interpreting figurative language in

individuals with autism. The first theory suggests that this is due to a cognitive deficit in “theory of mind,” or the ability to attribute mental states to self and to others, which leads to impairments in imagination, socialization, and communication (Happé 1995). Since metaphor requires the listener to be able to understand the speaker’s intention, an individual with autism might interpret the language literally and be unable to infer the intended meaning of the metaphor. The second theory proposes that poor figurative language comprehension is related to deficits in structural language skills, including vocabulary and syntax (Whyte et al. 2014).

Figurative language is ubiquitous in social communication, and, therefore, challenges interpreting figurative language can affect social relationships, social participation, and educational achievement (Kalandadze et al. 2016).

DeGangi-Berk Test of Sensory Integration

Tara J. Glennon

Occupational Therapy, Quinnipiac University,
Hamden, CT, USA

Centre of Pediatric Therapy, Fairfield and
Wallingford, Wallingford, CT, USA

Synonyms

DeGangi-Berk; TSI

Description

This assessment tool offers an objective method to examine the sensory functioning of children aged 3–5 years. This 36-item assessment published in 1983 intended to provide an objective method to determine whether, and to what extent, a preschool child had sensory processing deficits so that the practitioner did not need to rely on clinical judgment alone. At that time, there were only measurements of motor functioning with no other instrument sufficiently sensitive to determine if these motor issues were caused by an underlying sensory integrative difficulty.

Once the items are scored, they are calculated to establish an overall score of sensory integrative functioning (total test score), as well as a score within each of the following subdomains of sensory integration:

DeGangi-Berk Test of Sensory Integration, Table 1 TSI subdomains of sensory integration. All information taken from TSI test manual (p. 1–2)

Sensory integrative subdomain	Names of individual tests	Description and significance
Postural control	• Monkey task • Side-Sit • cocontraction • Prone on elbows • Wheelbarrow walk • Airplane • Scooter board • cocontraction	• Stabilization of the neck, trunk, and upper extremities • Muscle cocontraction of the neck and upper extremities • Includes antigravity postures
Bilateral motor coordination	• Rolling pin activity • Jump and turn • Diadochokinesis • Drumming • Upper extremity control	• Emphasizes bilateral motor coordination • Includes components of laterality including trunk rotation, rapid unilateral and bilateral hand movements, and crossing the midline • Includes stability of the upper and lower extremities in bilateral symmetrical postures and disassociation of trunk and arm movements
Reflex integration	• ATNR – asymmetrical tonic neck • STNR – symmetrical tonic neck • Diadochokinesis	• Quadruped position to observe asymmetrical and symmetrical tonic neck reflexes and associated reactions of the upper extremities

1. Postural control
2. Bilateral motor integration
3. Reflex integration

The above subdomains were identified for inclusion “because of their clinical significance in the development of sensory integrative functions in the preschool child” (DeGangi and Berk 1983, p. 1). Table 1 outlines the components of each subdomain.

This tool was designed to be implemented by occupational or physical therapy practitioners given their training and educational background in the interpretation of sensory integrative information and test results. Therefore, it is suggested that a practitioner outside of these fields (i.e., special educators or motor development specialists) seek the assistance of an occupational or physical therapist for the interpretation of the test scores.

With a baseline understanding of sensory processing, implementers should allow 2 h to learn the items prior to implementation. The assessment

manual is easy to follow, and the specific instructions for item implementation are outlined with pictures to assist. A score of 0 through 1, 2, 3, or 4 is received depending on the child’s response to each item and the quality of the performance indicating that the skill has been developed. The higher the score indicates a more integrated, organized, or normal response. Lower scores qualify the child’s responses, for example, unable to hold, loses grasp, does not cross [midline], no resistance, slight to moderate flexion of the elbow, etc.

The score tallies in each subdomain then result in a “normal,” “at risk,” or “deficient” score profile for a total test score, postural control score, bilateral motor integration score, and a reflex integration score (which is only counted toward the total test score). Score ranges for the varying age ranges are provided on the score sheet which makes scoring very clear. This criterion-referenced assessment tool offers clinicians working with this population of children a structured and organized method to assess sensory integrative functions in children with delays in sensory,

motor, and perceptual skills, or children suspected of having learning problems.

Historical Background

Georgia DeGangi, PhD, OTR (occupational therapist who now practices in clinical psychology) and Ronald Berk, PhD (professor of educational research at Johns Hopkins University at the time and authored the 1980 book titled: *Criterion Referenced Measurements: State of the Art*) developed this objective tool to observe and measure the sensory integrative processes in preschool children, specifically the vestibularly based functions of postural control, bilateral integration, and reflex integration. It was thought that difficulties in sensory integrative processing in preschool children could result in fine or gross motor delays, poor balance, poor hand use, distractibility, and/or visual-spatial organization later in the school years. Rather than wait for these secondary issues to arise, it was thought that intervention could addressed/remediated the sensory concerns before secondary issues arose. This thought, based on sensory integration theory (Ayres 1964, 1972, 1979), continues today. A fuller description of Ayres’ theory of sensory integration can be

found in the links below titled Ayres, A. Jean, sensory processing, and sensory integration therapy.

Psychometric Data

DeGangi began developing test items in 1978, completed psychometric studies, revised the test and the items, completed several rounds of reliability and validity testing, and ultimately identified 73 items. After additional item analysis, which discarded items that did not well discriminate typical from delayed children or were not sufficiently sensitive to typical developmental in these age ranges, only 36 items remained.

The test manual specifically outlines each step of the sampling and statistical procedures. However, it should be noted that there were some sampling difficulties resulting in a disproportionate number of 3–4-year-old children and a low sample population (*n*). The authors therefore suggest that further research with a more representative sample would improve the utility of the tool and the generalizability of the findings.

Table 2 outlines the components of the assessment process including the psychometric procedures associated with the development of this

DeGangi-Berk Test of Sensory Integration, Table 2 DeGangi-Berk TSI assessment review form

Test name: DeGangi-Berk Test of Sensory Integration (TSI)
Author(s): Georgia A. DeGangi PhD, OTR and Ronald Berk, PhD
Publisher: Western Psychological Services, 625 Alaska Ave, Torrance, CA 90503; 800-648-8857
Technical information: 2 h of practice before administering
Age range(s): 3–5 years old
Assessment type: Criterion referenced
The following information was obtained from the TSI Manual
Reliability:
1. <i>Interobserver reliability:</i> Two pairs of examiners were used. Difficulties with implementing repeat testing procedures resulted in a low number in the sample and not fully representative of each age group (i.e., no 5-year olds). Intraclass correlations were .80 and above for postural control, bilateral motor integration, and the total test; and coefficients for the dependability of each observer ranged from .67 to .79 for those same categories. Reflex integration was low within each pair of examiners as well as inconsistent between two pairs of raters.
2. <i>Decision-consistency reliability:</i> The <i>p_o</i> index of decision consistency was used determine “the proportion of children classified as normal and delayed on repeated testings” indicating a degree of confidence for the decision (i.e., the stability of the decisions). A sample of 23 “normal” and 6 “delayed” 3–5-year-old children (10 boys and 19 girls) were tested twice during a 1-week retest interval. Utilizing three observers, the <i>p_o</i> estimates for the three subtests and the total test ranged from 79–93% with the lowest in reflex integration. However, standard error was large and thought to be the result of the small sample size.

(continued)

DeGangi-Berk Test of Sensory Integration, Table 2 (continued)

3. *Test-retest reliability*: The Pearson correlation coefficients between test and retest scores for each subtest and the total score for a period of 1 week ranged from .85 to .96. Postural control was the least stable with anticipation/familiarity with the task thought to be an influence in the second testing, whereas bilateral motor integration and reflex integration, requiring more automatic responses, were thought to be less susceptible to performance changes on test-retest.

Validity:

1. *Content validity*: A two-stage judgmental review occurred to determine test validity.

- *Item-behavior congruence*: Item-behavior congruence and representativeness was rated by eight judges (occupational therapists). The degree of congruence between the items and the subdomain was rated either as poor, moderate, or high for each item. A rating of “high” was obtained for all items in postural control and reflex integration, and for all but one judge for bilateral motor integration.

- *Representativeness*: Twelve judges were asked: Is each collection of items representative of its respective subdomain of behaviors? A score of “high” was obtained by all judges for postural control and 87% of the judges for the bilateral motor integration and reflex integration (with the other 13% scoring as “moderate”).

2. *Construct validity*: Construct validity evidence was found within the item, subtest, and test, and because the specific use of the test score was to identify normal vs. delayed, this was the primary focus of the analysis. Total of 139 children in the sample.

- *Item validity*: The effectiveness of each item was found by computing a discrimination index (DIS) displaying the difference between the mean score for each item in the normal and delayed groups. Statistical significance was then computed using a *t* test and the magnitude of the significance computed via effect size (*d*). Out of the original 73 test items, 37 were taken out after item analysis since they did not discriminate between the groups of delayed and normal, or were not sensitive to the normal developmental status of this population.

- *Decision validity*: The cut-off scores for this tool, and therefore the focus of these analyses, were to minimize the false normal error rate as this was thought to be the most serious of errors. The total test and the three subtests’ error rate ranged from 4 to 9%. The error rate for false delayed ranged from 10 to 26% for all test scores. Sensitivity and specificity were calculated with scores of 71% and 85%, respectively, for the total test.

- *Test structure*: Moderately low subtest correlations (.39–.65) confirms that each subtest is measuring different vestibularly based functions, thus supporting the structure of the test. The correlation of the subtests to sensory integration as a whole ranges from .64 to .93. There was also support that the subdomains of postural control and bilateral motor integration were more vital to overall sensory integration than reflex integration.

Testing procedures

Obtaining information: Thirty-six items should be administered individually and in one sitting; items should be administered exactly as described in the order presented in the manual.

Time to administer: 30 min

Time to score: 10 min

Materials included in the test kit? ☒ yes ☐ no

Additional materials needed: 10 × 15 ft. space, table and chair, masking tape, pencil without eraser, switch-back stopwatch, 3-ft-long wooden dowel, rolling pin, carpeted scooter board, plastic hula hoop, and floor mat

Is the tool easy to learn and administer? ☒ yes ☐ no

How much training or practice is required? 2 h

Who can administer the test? Designed for implementation by occupational therapists and physical therapists; can be implemented by special educators or motor development specialists but seeking an occupational or physical therapist to interpret whether the score is recommended as they have training and education in sensory processing.

Is the manual easy to follow/understand? ☒ yes ☐ no

Are the forms easy to follow/understand? ☒ yes ☐ no

The forms are very clear, easy to follow while administering, and can be quickly scored in a very objective manner.

Domains: Postural control, bilateral integration, and reflex integration

criterion-referenced assessment tool. In summary, the total test score can be used reliably and validly for screening decisions, and the postural control score and bilateral motor integration score can be used reliably and validly for diagnostic decisions based on the following information:

1. **Domain validity:** The total test had a high degree of domain validity

- Consensus among therapists that the items measure the behaviors they were designed to measure, and that the collection of items composing each subtest was representative

of the behaviors defined by the subdomains. (DeGangi and Berk 1983, p. 40)

2. Construct validity:
 - Total test score can be used for screening decisions with better than 80% accuracy and a 9% false normal error rate.
 - Postural control and bilateral motor integration subtests were extremely accurate.
 - Reflex integration was the least effective subtest.
3. Interobserver reliability:
 - Very reliable for postural control, bilateral integration, and total sensory integration behaviors.
 - Considerable subjectivity for reflex integration behaviors.
4. There were high levels of classification consistency in the identification of the classification designated for each item.
5. Test-retest reliability:
 - The results provided substantial evidence of the stability of sensory integrative functions for a 1-week re-test interval using a homogeneous preschool sample. (DeGangi and Berk 1983, p. 41).

Clinical Uses

Any assessment tool should be used in combination with other tools in order to gain the most comprehensive picture of a child's functioning. The DeGangi-Berk TSI was intended to provide information related to the three subdomains noted above as these categories of sensory integrative functioning were thought to have a strong impact on the development of sensory integrative functions in the preschool child. The intent was to administer this assessment to children with delays in sensory, motor, and perceptual skills, or to children suspected of having learning problems.

This tool continues to be utilized today in clinical practice as it is a structured and organized method to investigate the sensory processing abilities in this age group.

Deictic Terms

Sarita Austin

Unlocking Language, London, UK

Synonyms

Deixis

Definition

Deictic terms are words whose meaning shifts depending on the point of view of the speaker. Examples of deictic terms include “this/that,” “here/there,” “I/you,” and “my/your.” While some personal pronoun contrasts (“I/you,” “my/

your”) are expected to develop before 3 years of age, many typically developing children continue to have difficulty with spatial contrast deictic terms (“this/that,” “here/there”) into the early school age years. This difficulty is thought to be related to the shifting quality of the referents for these terms. That is, “I” does not refer to any particular person but to the person who happens to be talking at a given time. When that person stops talking, the referent for “I” shifts to the next speaker. “Here” refers not to a specific location but rather to a place near the speaker. What is “here” for the speaker may be “there” for the listener. This shifting reference is thought to cause special difficulty for speakers with ASD, possibly due to their difficulties with perspective taking, communicative engagement, flexibility, and change. It is important to note that young children with typical development can also have difficulty with deictic terms.

Delaware Autism Program

Vincent Winterling

Delaware Autism Program, Newark, DE, USA

Major Areas or Mission Statement

The Delaware Autism Program (DAP) is one of the largest public school programs in the United States specializing in educating children and adolescents with an Autism Spectrum Disorder (ASD). In 2019, it served in excess of 1500 students between 2 and 21 years of age, in the full range of settings (residential programs, separate schools and settings, and integrated school and community sites) in six affiliated school districts. DAP sites employ more than 500 staff, including teachers, assistants, specialists (psychologists, behavior analysts, speech language pathologists, occupational therapists, nurses, etc.), and administrative and support staff.

Retired (former Statewide Director of Autism).

Landmark Contributions

Elements of DAP have been described in various book chapters (Battaglini and Bondy 2006; Bondy 1996; Bondy and Frost 1994, 1995; Doehring and Winterling 2011). The Picture Exchange Communication System (PECS) (Frost and Bondy 2000) was first developed by Andy Bondy and Lori Frost during their tenure at DAP, together with the involvement of other DAP staff. Statewide directors have included Dr. Andy Bondy (1981–1997), Dr. Peter Doehring (1999–2008), Dr. Vincent Winterling (2009–2019), Dr. Mary Whitfield (2019–present).

Major Activities

DAP is public school program that presently consists of affiliated programs in 6 of the 19 school districts (Local Education Agencies, or LEA) across the 3 counties in the State of Delaware, plus other specialized services and supports (e.g., full year programming, respite, and temporary residential), provided through the Office of the Statewide Director of Autism. As a public school program, DAP's services are fully funded by the LEA and the State Education Agency (SEA), at no cost to parents. The six affiliated programs share many key elements, including: (a) programs for children 2 up until 21 years of age, across the autism spectrum; (b) settings ranging from full inclusion to separate classroom for children with ASD, including extended school year services; (c) reliance on teaching methods based on principles of Applied Behavior Analysis (ABA), including PECS; (d) a high staff to student ratio to support more individualized teaching and community integration; (e) opportunities for parents to create local Parent Advisory Committees (PAC) to provide input to the LEA, SEA, and Office of the Statewide Director of Autism; (f) expectations that staff complete a core training program, which for teachers includes a 15-credit graduate teaching certificate in autism and (g) oversight of the program provided by external experts in collaboration with program administration. Many of the programs also coordinate with

other organizations (i.e., daycares, vocational settings, institutes of higher education) to provide community-based services. Three of the six programs operate larger county centers which provide education services to students with more challenging educational and behavioral needs. Through an agreement with the SEA, the Office of the Statewide Director of Autism provides services across the state, including: (a) management of extended educational services (temporary residential programming in community-based settings) and extended support services (in-home respite provided to parents for a nominal co-pay); (b) leadership of various statewide committees that provide consultation to LEAs regarding educational programming, to coordinate parent input from the PACs and provide independent peer review of the assessment and intervention for students with very challenging behaviors; (c) coordination of staff training specific to ASD, and; (d) consultation to all school districts in the state on challenging students. DAP was established in 1976 after parents helped to pass laws defining many of the core elements of the program (specialized positions like the Statewide Director, specialized services like extended educational and support services, additional staffing, extended school year, statewide committees, etc.).

Delay, Deviance Versus

Elizabeth Spencer
College of Education and Human Ecology, The
Ohio State University, Columbus, OH, USA

Definition

Delay versus deviance refers to a debate about the nature of development in autism and other disorders. In general, a child who exhibits a developmental delay follows a progression of development found in the general population, but progress in development at a slower rate. In contrast, a child who exhibits deviance follows a progression of development that is different both in rate and sequence of progression. There is evidence to suggest that children with autism may follow a developmental progression that includes elements of both delay and deviance. In many children with autism, language development is often delayed but occurs in a progression similar to children with typical development. In other children, language development may also include deviant characteristics (e.g., echolalia).

Many children with autism demonstrate deviance in the development of social and pragmatic skills. For example, some children with autism demonstrate deviance in the development of social behaviors such as joint attention.

Demographics and the Age of Autism Diagnosis

Judah Koller
Seymour Fox School of Education, Clinical Child Psychology, The Hebrew University of Jerusalem, Jerusalem, Israel

Definition

The role of social and demographic factors on the age at which children are diagnosed with ASD.

Historical Background

A growing body of literature has shed light on the nature of the rapidly rising prevalence of ASD.

Several variables have been suggested in attempts to explain this trend, with the primary question focusing on whether there is an actual rise in incidence or if an increase in awareness has led to higher rates of diagnosis. Variables such as parental age and environmental pollutants have been suggested as influencers of diagnostic trends (Durkin et al. 2008; Raz et al. 2015a). From the social perspective, contributing factors appear to include increased awareness of ASD, changes in the tools used in screening and diagnosis, lower levels of stigma in societies, and shifts in the diagnostic criteria (Leonard et al. 2010). Taken together, the general consensus appears to be that, while the former factors may play a modest role, the rise in incidence is not a true increase in the rates of ASD but rather a social shift expressed in higher numbers of individuals being accurately identified and diagnosed (Isaksen et al. 2013).

Given the above, it follows that these social factors affecting the rates of diagnosis of ASD play out in variable fashion across social and demographic contexts. In the ongoing work by the Centers for Disease Control and Prevention's (CDC) Early Autism and Developmental Disabilities Monitoring (ADDM) Network, national prevalence estimates are based on the average across the states monitored. Within that data exists tremendous variability, strengthening the claim that social factors are central in determining rates of diagnosis (Christensen et al. 2019). In a recent publication evaluating data from 2014, the state with the lowest prevalence was Missouri, at approximately 1 in 104 children. The highest prevalence was found in New Jersey, at 1 in 35. Given the lack of any environmental or biological explanations for this stark discrepancy, it is most logically by the fact that New Jersey has more capacity in the form of trained experts with the ability to diagnose young children as well as an early childhood education system capable of screening for and identify the children.

Notably, even with increased awareness, more accurate diagnostic measures, and reduced stigma, families and children that are not seen by trained professionals with specific expertise in the diagnosis of ASD will not be identified.

Current Knowledge

Concurrent to the aforementioned increase in rates of diagnosis of ASD, the professional community's ability to identify and diagnose ASD in early childhood has improved dramatically. Much research now shows that an evidence-based diagnosis of ASD can be provided to most young children with a high degree of confidence between the ages 18 and 24 months and that such diagnoses are typically stable, meaning they remain accurate when the same child is reevaluated at older ages (Guthrie et al. 2013; Ozonoff et al. 2015). Despite these significant advances in our understanding of the early presentation of ASD and our ability to make accurate early diagnoses, the median age at which a child in the United States receives a diagnosis of ASD is 52 months (Baio et al. 2018).

A number of factors appear to contribute to this significant and costly delay in the age at which children are diagnosed. Children with less pronounced autism symptomatology are often diagnosed later compared to children with higher levels of symptom severity, as are children with average verbal abilities, in contrast to those who are minimally verbal (Salomone et al. 2016). The same is true for children from families with low socioeconomic status (SES) and those whose parents do not express concern regarding the presentation of primary symptoms. On a systemic level, children who do not have access to education and health services are often diagnosed later than peers who have such access (Daniels and Mandell 2014; Mazurek et al. 2014; Shattuck et al. 2009).

Children with comorbid health problems or behavioral difficulties are also likely to receive a diagnosis later, since parents or professionals could potentially attribute symptoms of ASD to these co-occurring conditions (Mandell et al. 2005). Such a situation often leads to an incorrect primary diagnosis of another disorder or a missed diagnosis altogether due to diagnostic overshadowing (Fombonne 2005; Goldstein and Schwebach 2004). For similar reasons, children with autism who have experienced adverse childhood experiences, defined as stressful or traumatic experiences, are likely to receive a diagnosis of ASD later than peers who do not have these experiences (Berg et al. 2018).

Specifically related to SES, studies have consistently found a link between high SES, represented by income, parents' profession, and/or years of parental education, and increased rates of ASD (Durkin et al. 2017; Ng et al. 2017). The primary explanation proposed is that with higher parental education and financial means comes increased access to services, including ASD diagnostic services (Durkin et al. 2010, 2017; Thomas et al. 2012). Work in the United States has found children with ASD from families that speak English as a second language receiving school-based services later than children who come from English-speaking families. When they do eventually receive the services, they receive fewer hours each week than their peers (Nguyen et al. 2016). In contrast, some studies from outside the United States found no particular association between SES and age of diagnosis, and some even found an inverse relationship between family income or parental education and ASD incidence (Khaiman et al. 2015; Larsson et al. 2005). Interestingly, in countries with universal healthcare, such as Canada, Norway, Sweden, and France, where disparities in access to health services between socioeconomic classes are low, higher ASD prevalence was found in lower SES groups, or no link was found between SES and prevalence of ASD (Burstyn et al. 2010; Delobel-Ayoub et al. 2015; Rai et al. 2012).

An extensive review conducted by Daniels and Mandell (2014) examined the association between SES, ethnic or race affiliation, and age of diagnosis. Of the 11 studies that inspected the relationship between SES and age of diagnosis, 5 found an association between high SES and earlier diagnosis, while the remaining studies found no such association. Twelve studies examined the association between ethnic or racial affiliation and the age of diagnosis and revealed contradictory findings. Five of the 12 found that children belonging to ethnic or racial minorities were likely to receive a later diagnosis compared to children of nonminority children, while 5 other studies did not find a correlation between these factors. The remaining two studies found mixed results, showing that children of the main ethnic group were likely to receive a later diagnosis

compared to children of ethnic or race minorities. The researchers posit that these dyssynchronous findings can be attributed to variables that differ between the reviewed studies, such as study duration, sampling method, and the geographic location of the study. The variable findings in this body of literature demand a more nuanced assessment of each individual study, which must each be interpreted within its particular respective context. For instance, a Norwegian study found that ethnicity did not influence the age of diagnosis (Larsen 2015). However, it is imperative to contextualize this finding within the political reality of Norway, where every child has access to health and developmental care at community healthcare centers, regardless of any ethnic difference.

As indicated above, societal shifts in awareness and understanding of ASD are clinically significant and relevant in societal contexts where children and families are able to access proper care. A consistent source of medical or developmental care is essential in order for children to be diagnosed in timely fashion (Emerson et al. 2016). Families with lower SES are also less likely to have such a consistent source of care, thereby minimizing the chance that developmental delays of any kind will be identified and targeted close within the optimal timeframe.

It is noteworthy that the association between consistent care and age of diagnosis was found to differ based on race (Emerson et al. 2016), with African American children's age of diagnosis not decreasing in correlation with consistent care. This could potentially be explained by way of differences in parent and/or professional behavior. Professionals seeing young children of low SES African Americans may be slower to refer the child for a full diagnostic evaluation. Alternatively, or simultaneously, the parents of these children maybe slower to push for such a referral or to question a "wait-and-see" approach.

screening and diagnosis are critical. The conflicting findings that exist in this body of literature point to fact that we do not have a clear understanding of these issues. While some studies find strong associations between variables such as SES and age of diagnosis, others do not. Without considering the context for these studies, we are unable to decipher the meaning of the body of work as a whole.

For instance, while studies have examined differences between ethnic and racial groups within the United States, few have done so internationally. A recent study from Israel (Koller et al. 2019) found that the Arab children diagnosed in Jerusalem prior to the age of 6 were nearly all minimally verbal and displayed severe autism symptomatology. While small, this study highlights the fact that while large-scale, population-based studies are necessary to understand broader trends, more nuanced examinations of specific populations and regions are necessary in order to gain actionable data that can lead to the support of specific sectors.

Significantly, the work done in this area has clear and direct relevance for public policy and community mental health. Efforts to raise awareness of ASD and improve capacity for identification of ASD by community professionals can assist in the early diagnosis of children. The heterogeneity of results seen across studies indicates that region-specific differences in screening, evaluation, and diagnostic practice affect the age of diagnosis. The findings of studies conducted in specific geographical regions or municipalities should be conveyed to policymakers and stakeholders in order to utilize the findings as stepping-stones to improved systems of public awareness, screening, and diagnosis. Continued improvements in these both research and research-driven practice may assist the provision of earlier ASD diagnoses and support, which could lead to improved developmental outcomes.

Future Directions

Further research and taking a more nuanced and subjective perspective on the process of

Dendrite

Claudia Califano

Yale-New Haven Hospital, New Haven, CT, USA

Definition

A dendrite is one of the four main parts of neurons, which also include the cell body, the axon, and the axon terminals. The dendrite is the part of the neuron that receives incoming signals from other neurons. The signals come in the form of neurotransmitters that cross the area of the synapse between one neuron and another neuron's dendrites. Neurotransmitters bind to receptors on the dendrites, and then the signal passes through the neuron to the cell body. Dendrites may have extensive branching, and each neuron often has multiple dendrites.

The number of dendrites and thus the number of synapses vary with the functions of a neuron. The dendrites of one neuron may receive signals from thousands of other neurons. That one neuron then integrates many signals received and responds accordingly.

Background

Autism spectrum disorder (ASD) encompasses early-onset neurodevelopmental mishaps afflicting about 1 in every 160 children worldwide. It develops through a complex set of etiologies that involve immunological, environmental, and genetic factors (Jia et al. 2018a, Bjørklund et al. 2019). Individuals diagnosed with ASD may display a range of problem behaviors such as hyperactivity, poor attention, impulsivity, aggression, self-injury, and tantrums. The lack of successful therapy, genetic heterogeneity, and the increasing incidence make it one of the most challenging disorders. At present, only some comorbid problems of ASD could be treated, but

not the core manifestations (El-Rashidy et al. 2017; Cheng et al. 2017; Shaaban et al. 2018). The etiopathogenesis of ASD is complicated and debatable. Immunological abnormalities have been recently linked with the pathology of ASD. The chemosensory immune system has a vital role in the process of neurodevelopment by regulation of the neuronal proliferation, plasticity, and synapse development. Besides, it removed the apoptotic neurons and contributed to numerous neurological activities (Wang et al. 2014; Bjørklund et al. 2016). Numerous revisions over the last 20 years have recognized immune disorders, including both decreased immune functions and higher autoimmunity among children diagnosed with ASD (see for details Bjørklund et al. 2016). Immune system abnormalities may have a role in autism development; however, there is no consensus regarding whether these disorders initiate the onset of core manifestations or regulate the symptomatology and pathogenesis of autism (Wang et al. 2014). Individuals with ASD are more susceptible to various types of infections, asthma, allergies, and seizures. Also, autistic patients usually have peculiar reactions to vaccines and autoimmune diseases (Hsiao 2013; Wang et al. 2014; Bjørklund et al. 2016).

Dendritic Cells

Dendritic cells (DCs) currently are known as a distinct hematopoietic lineage of myeloid cells, together with monocytes, granulocytes, and macrophages. They originate from the bone marrow (BM) through specific ancestor subclasses and actively contributed to both adaptive and innate immunity and managing the equilibrium between tolerance and immunity. DCs are powerful phagocytic cells and considered one of the most effective specialized antigen-presenting cells (APCs) that are required for initiation and spreading the immune responses (Rhodes et al. 2019). DCs are responsible for uptaking, processing antigens, and then presenting them to T-lymphocytes (Patente et al. 2019). DCs recognize antigens via Toll-like

receptors, which are specific for certain molecules present in bacteria, fungi, viruses, and parasites (Patente et al. 2019). In the peripheral blood, DCs are immature that upon stimulation give rise to two active forms. Based on the functional and phenotypic features, DCs are classified into two lineages. The first type is myeloid dendritic cells (mDCs) CD11c+CD123−, also called conventional DCs, which present mainly in the peripheral blood and lymphoid tissues. mDCs represent the antigen-presenting dendritic cells that summit the adaptive immunity (Patente et al. 2019; Rhodes et al. 2019). mDCs are highly specialized cells similar to monocytes and are secondly divided into *mDC-1* cells which are the main stimulator of CD8⁺ cells, which is very important in antiviral and antitumor activity (Brewitz et al. 2017), and the less common *mDC-2* cells which have several immunoregulatory functions. They are potent inducers for Th1, Th2, and Th17 immune responses. Also, mDC-2 activate T-regulatory cells in the gastrointestinal tract. In addition, mDC2 stimulate CD4⁺-naïve T-lymphocytes to express gut-homing molecules (Segura et al. 2012; Leal Rojas et al. 2017).

The second type is plasmacytoid dendritic cells (pDCs) CD11c−CD123+, which are found in small numbers in the peripheral blood. pDCs have a potential role as APCs, as they express co-stimulatory molecules and MHC II. Also, they have an antiviral role through the production of interferon I and III and priming CD8⁺ T-lymphocytes and natural killer cells (Schlitzer et al. 2018; Rhodes et al. 2019).

Costimulatory Molecules B7 (CD80/CD86)

CD80 and CD86 are a group of cell surface glycoproteins of the B7 family, structurally related to immunoglobulins. These molecules play an important role in the regulation of innate and adaptive immune system (Rhodes et al. 2019). Previous studies have reported that B7-1 (CD80) and B7-2 (CD86) are the most characterized

costimulatory molecules for activation of T-lymphocytes (Fujii et al. 2004; Schlitzer et al. 2018). CD80 is expressed in low levels on the surface of DCs, APCs and monocytes; however, CD86 is highly expressed in these cells. CD80 and CD86 can either stimulate T-lymphocytes through binding to CD28 receptor or deactivate T-cells through binding to CTLA-4 (cytotoxic T-lymphocyte-associated antigen) receptor. CD80 and CD86 are exclusively essential in DCs' activation. When the MHC class II peptide on DCs interacts with T-helper cells, CD80 and CD86 are upregulated, allowing the activation of DCs and contact them to CD8⁺. This supports T-lymphocyte differentiation into cytotoxic T-cell (Fujii et al. 2004; Zheng et al. 2004).

As stated before, these costimulatory molecules have a pivotal role in DCs activation. This activation occurs through CD28 interactions with increase the mobility of DCs for migration and release of cytokines specifically IL-6, with activation of cellular proliferation, and inhibit apoptosis (Zheng et al. 2004; Schlitzer et al. 2018). On the other hand, these molecules have inhibitory effects on DCs through interaction with CTLA-4. This suppressive effect helps regulatory T-lymphocytes to avert any immunological response to self-antigens (Fujii et al. 2004; Zheng et al. 2004).

Dendritic Cells and Costimulatory Molecules in Autism Spectrum Disorders

In our previous work (Saad et al. 2017), we assessed the levels of DCs and CD86 and CD80 costimulatory molecules in children with ASD and compared to normal children:

Myeloid Dendritic Cells (mDCs)

Our study showed significantly augmented levels of mDCs in children with ASD when compared to typically healthy children (2.44 ± 0.20 vs. 1.54 ± 0.09 ; $p = 0.006$). Furthermore, we noticed positive correlations between the frequency of mDCs and autism severity

($p < 0.01$), stereotypy ($p < 0.05$), social understanding ($p < 0.001$), emotional response ($p < 0.01$), and hyperactivity ($p < 0.05$), as measured on CARS and ABC scales (Saad et al. 2017). In line with our findings, Breece et al. (2013) reported significantly increased mDCs frequencies in autistic children as compared to normal controls ($4.6\% \pm 0.41$ vs. $3.70\% \pm 0.38$; $p = 0.03$). They found the percentages of mDCs were higher by 25% to 40% in autistic patients when compared to normal children. Besides, they found significant positive correlations between the frequency of mDCs and stereotypic behavior ($p = 0.02$; effect size = 0.43) and the severity of GIT symptoms especially constipation ($p = 0.002$; effect size 1.85) (Breece et al. 2013). In addition, they reported significant positive associations between mDCs and the volume of the left amygdala ($p = 0.004$), and right amygdala ($p = 0.02$), in autistic children after adjustment of sex and age of the patients' group.

Plasmacytoid Dendritic Cells (pDCs)

In our study, pDCs' frequencies were higher in autistic patients when compared to controls ($1.98\% \pm 0.35$ vs. $1.18\% \pm 0.05$; $p = 0.036$). Furthermore, we found a positive association between mDCs and autism severity ($p = 0.05$). However, we could not find any correlations with autism core manifestations and pDCs (Saad et al. 2017). Contrary to our results, Breece et al. (2013) reported comparable frequencies of pDCs in ASD patients and typically developing controls. They reported significant correlations between pDCs percentages and the right amygdala ($p = 0.03$) and left amygdala volumes ($p = 0.02$) (Breece et al. 2013).

Costimulatory Molecules CD80 and CD86

Our data showed a significant upregulation in the expression of CD80 (49.67 ± 4.67 vs. 23.16 ± 1.39 ; $p = 0.001$) and CD86 (55.37 ± 2.94 vs. 39.42 ± 4.7 ; $p = 0.001$) costimulatory molecules on the entire DCs in autistic children when compared to control group. In addition, the mean fluorescent intensity of CD86+ (149.36 ± 9.52 vs. 111.26 ± 8.26 ; $p = 0.003$) and CD80+ (76.07 ± 3.18

vs. 52.05 ± 3.59 ; $p = 0.001$) were significantly higher in ASD group than controls (Saad et al. 2017).

For the first time, our results showed an inverse association between the frequencies of both types of DCs and vitamin D levels in autistic children. Recently, many pieces of research and reviews focused on the role of vitamin D in CNS and immunological disorders (Saad et al. 2016; Björklund et al. 2016, 2019; Jia et al. 2018a). In addition to the well-known metabolic functions of vitamin D in bone and mineral metabolism, plentiful studies reported that vitamin D has several functions in the process of brain development by affecting the axonal connectivity and neuronal differentiation. In ASD, previous studies have shown significant associations between vitamin D deficiency and increased risk of autism (for details see Jia et al. 2018b). Additionally, vitamin D deficiency during pregnancy was associated with numerous adverse effects on the fetus, e.g., intra-uterine growth retardation (Björklund et al. 2016; Jia et al. 2018b). Vitamin D is a key modulator of the immune system, playing an important physiological role in the regulation of both adaptive and innate immunity. Vitamin D is shared in the process of DC maturation and affected their functions through multiple mechanisms. In DCs, vitamin D can make a resistant phenotype with low HLA-DR, CD80, and CD86 expressions with a high ratio of interleukin10/interleukin12p70 (Ferreira et al. 2015). Furthermore, the differentiation of DCs in the presence of active form of vitamin D ($1,25D_3$ -DCs) leads to failure of DCs to stimulate autoreactive T-lymphocytes, activating in its place antigen-specific T-regulatory cells resulting in induction of infectious tolerance and preservation of DC tolerogenic response (Ferreira et al. 2014, 2015).

Conclusion

Taken together, the previous data suggest many systemic immune abnormalities in patients with ASD. Significant variations in the frequencies and functions of the myeloid lineage cells, specifically DCs, macrophages, and monocytes, have been

extensively investigated in many types of research in children with ASD (see Bjorklund et al. 2016 for details). We suggested that DCs may play a role in the pathogenesis of ASD. However, the exact mechanism of the correlations of DCs and their costimulatory molecules in ASD remains to be elucidated.

Dental Care

Ben Popple¹ and Fred R. Volkmar²

¹White Oak Pediatric Dentistry, Newnan, GA, USA

²Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

Dental care is just as important (if not more important) for children with autism. Unfortunately, various factors make attaining adequate dental care challenging for children with autism. While parents are understandably reluctant to stress their child – particularly a child with oral sensitivities – lack of dental care early in life can lead to major long-term health problems (Volkmar and Wiesner 2009).

Historical Background

As noted elsewhere in this volume, a considerable body of work on the nature of autism and related conditions (Autism Spectrum Disorders, ASDs) exists. These conditions are characterized by major problems in social interaction, communication, and behavior. These individuals range from intellectually deficient to above average IQ. Unfortunately, deficits described above can make providing quality dental health care difficult and unpredictable (Stein et al. 2014). In addition

to difficulties completing dental treatment, parents also have difficulty accessing care (Kogan et al. 2008) or may avoid care because of stress related to appointment experience (Weil and Inglehart 2012). For these reasons, managing their oral health can be very challenging for health care providers.

Current Knowledge

As with regular medical care, establishing a “dental home” is a major step forward in providing comprehensive ongoing dental care for children with autism (Nowak and Casamassimo 2002). Unfortunately, finding a dental home can be difficult because very few general dentists are comfortable treating these individuals because of behavior challenges. Some sources report fewer than one in ten general dentists will treat individuals with special health care needs (Casamassimo et al. 2004). As a result, individuals with autism are often forced to visit multiple offices before finding a dentist who is willing to treat them. Frustration associated with this process can be avoided when patients specifically seek out a pediatric dentist to treat their child’s dental needs. Pediatric dentists complete a 2-year residency program in addition to dental school. In residency, they learn to provide dental care for infants and children through adolescence, including patients with special health care needs. Many pediatric dentists will continue to see patients with special health care needs such as autism well into adulthood. As patients get older, they may start to develop some oral health needs that pediatric dentists are not comfortable addressing. Pediatric dentists can be a helpful resource for finding caregivers who treat more adult needs and are comfortable treating patients with autism.

When searching for a pediatric dentist, parents should be aware that locating a pediatric dentist currently accepting new patients might be difficult (Capozza 2012). The availability of pediatric dental practitioners varies widely by state. Additionally, lower reimbursement by state insurance programs like Medicaid may pose further obstacles for care. The American Academy of Pediatric

Dentistry has developed a provider search engine to help parents find pediatric dentists in their area (<http://www.aapd.org/finddentist/>).

Oral Health Concerns. Individuals with ASD experience many oral health conditions requiring management by dental professionals similar to the general population. Like the general population, the most commonly reported oral health concern individuals with ASD experience is dental decay (Stein et al. 2012). In addition to dental decay, other commonly reported oral health problems include periodontal disease, dental trauma related to coordination problems, and dental trauma related to self-injury (Volkmar and Wiesner 2009). Individuals with ASD also experience orthodontic problems like anterior open bite, crowding, and diastema (Delli et al. 2013).

It is important to understand that dental decay is an enormous problem for all children in the United States regardless of health status. Dental decay is the most common chronic childhood disease today with an estimated 16 million children currently affected. Oral disease is responsible for children missing 51 million school hours and parents missing 25 million work hours annually. Children from low-income families have significantly more untreated decay than the rest of the population.

Considering the high rate of decay experienced by the general population, one may expect individuals with autism to also experience a high rate of dental decay. Current studies, however, do not give clear confirmation that this is the case. Although it is generally agreed that there is a higher risk for dental caries in ASF although data addressing this is rather limited likely related to differences in samples studied (see Loo et al. 2008). Caries prevention in this population is an obvious priority.

Prevention

While the patient, parents, and dentist play the primary role in prevention of dental disease, all members of the health care team need to be aware of dental caries prevention strategies. Establishment of the dental home is the first step in this process preventing dental decay (Nowak and Casamassimo 2002). Ideally, the dental home

should be established within 6 months of the eruption of the first tooth or no later than 1 year of age. Similarly, the medical home should also be established at this time. One goal of the dental home is to break the current cycle of problem-initiated care seeking. The dental home works to help establish good oral health practices through patient and parent education. The dental home also identifies dental disease early in the disease process when it can be most easily managed. The dental home is also responsible for referral to the appropriate specialist when the patient's dental needs are beyond the scope of practice of the dental home.

Caries risk assessment is a tool that uses caries risk indicators to identify habits that are likely to result in the development of dental decay. Identifying these high-risk habits allows preventive strategies to be customized for each patient, so dental decay can be avoided and/or the decay process can be stopped when it is experienced (AAPD 2013). This is especially helpful for patients with ASD because of how little we know about this population's caries experience and the many caries risk indicators with which these patients can present. A risk assessment will ideally have sufficient data to accurately determine disease susceptibility and offer preventive strategies.

Beyond being broadly classified as high caries risk because of special needs status, individuals with autism also have risk factors specifically related to their disorder. Some risk factors include poor oral hygiene, detrimental oral behaviors, medication-induced xerostomia, concurrent medical diagnoses, low cognitive level, poor dietary habits, gastric reflux, a preference for soft/sweet foods, use of sweets for behavior modification, and requiring help with tooth brushing. Some risk factors occur more commonly than others in this population, but no child will display exactly the same risk factors.

The next strategy for preventing dental decay is increasing the patient and caregiver's knowledge through education (Klein and Nowak 1998). Caregivers and patients should have a basic understanding of how dental decay occurs so they can be proactive in making good oral hygiene

decisions. Everyone involved in the patient's care should be aware of the four factors that must come together for a cavity to form, i.e., presence of teeth, the presence of bacteria, the presence of a nutrition source for the bacteria, and time for the decay to develop. While the presence of a tooth and time cannot be modified easily, the other two factors can be. The first modifiable variable is the level of cariogenic bacteria in the mouth. The second factor is the level of fermentable carbohydrates present in the oral environment (Featherstone 2004).

Bacteria levels can be reduced through good oral hygiene (brushing twice per day with fluoride toothpaste and flossing once per day). Fermentable carbohydrates can be reduced through diet control (avoiding foods that are especially cariogenic). Caregivers have total control of diet in this situation and can help prevent decay by drastically reducing fermentable carbohydrates in the diet. In the case of a higher cognitively functioning individual, the child may have more independence when it comes to food choices. With this scenario, effective oral hygiene skills can be taught, therefore reducing bacteria level in the oral environment.

While diet and oral hygiene can both be targeted to reduce caries risk, improving oral hygiene may be the best way to reduce caries risk in the autistic population. Difficulty with home care can be explained by many of the same reasons, and treatment in the dental clinic is also difficult. Tooth brushing can cause problems with individuals who have oral sensitivity, poor motor control, poor understanding, and lack of interest. Fluoride is safe and effective at reducing tooth decay when used as directed (Volkmar and Wiesner 2009). In fact, the Center for Disease Control and Prevention considers water fluoridation to be one of the ten greatest public health achievements of the twentieth century with more than 150 million Americans benefiting from fluoridated water. If there is concern that a patient may swallow toothpaste, extra care should be taken to make sure the proper amount of toothpaste is used during each brushing session. Children under the age of 2 should only have a smear of toothpaste applied to the toothbrush, while children over the

age of 2 can use a pea-sized drop of toothpaste each time they brush (Guidelines on Fluoride Therapy 2014)

Visual teaching can also be used to help improve daily oral hygiene skills. Studies using a simple photo storybook to outline home care and in office procedures have helped improve procedural success (Volkmar and Wiesner 2009). Equally as important, in one study, parents saw the value in the intervention and continued using the storybook when the study ended (Backman and Pilebro 1999).

For the uncooperative child, various strategies may be employed, e.g., three-sided toothbrush. The three-sided toothbrush allows the parent to clean the buccal, lingual/palatal, and occlusal surfaces of the tooth all at once, reducing brushing time and increasing the chance of cleaning all tooth surfaces. Another helpful tool is the mouth prop. Mouth props are placed on the opposite side of the mouth from the side being brushed to prevent the child from biting down. Mouth props can be as simple as a stack of tongue blades taped together or the handle end of a toothbrush. Mouth props can also be purchased online from special needs dental supply websites. Finally, floss sticks and interproximal brushes can be used instead of traditional dental floss. These products may be easier to use when flossing a difficult child, because they can be used with one hand.

Appointment Preparation and the Dental Visit

Challenges for office visits for the child with ASD arise given the children often have difficulties with change, have limited communication skills, can be highly anxious, and variably related socially. These children may dislike being touched and may be alarmed by unusual sounds or bright lights. Accordingly, many behavior guidance techniques commonly used by dental professionals may be of limited use (Marshall et al. 2007). Thus success in the dental chair is largely dependent on preparation for the visit. Caregivers, like parents and therapists, can also do many things to help prepare the patient for the visit. At home, caregivers can help the patient prepare for the visit using exercises to familiarize the patient with what to expect at the appointment by

using visual aids and appointment practice (Pilebro and Backman 2005; Volkmar and Wiesner 2009). Parents are often quite good predictors of the child's behavior. Simply asking things like whether the child can sit for a haircut, if the child is toilet trained, and how successful tooth brushing is at home can serve as initial predictors of cooperativeness. It is important to understand parental concerns or questions, e.g., relative to fluoride, diet, behavior management strategies, and so forth. Parents may have questions about mercury or use of nitrous oxide, radiation, and other materials (Rada 2010). Strategies that can help include predict in use of the dental chair, and visual strategies have been successfully used to manage a range of problems and enhance compliance with health care and make use of the typical strengths children with autism have in the area of nonverbal, visual, static, and sequential information presentation (Hogdon 1995). Storybooks can demonstrate what the dental office, waiting room, and treatment rooms look like. The storybook can also show pictures of dental instruments and pictures of what the dental providers look like. These materials are readily prepared on today's computers and can be used to facilitate cooperation. Realistic goals should be set for each appointment. Staff should notice patterns of success and gradually build upon these. Understanding and consistency on the part of care providers is important, e.g., scheduling so as to avoid waiting time.

For the dental visit, applied behavior analysis (ABA) strategies can help interpret and modify behavior. It is also important for providers to understand that poor behavior can be unintentionally negatively reinforced the same way positive behavior can be reinforced. Children with autism often demonstrate oral defensiveness, escape, and avoidance behaviors at their dental visit attempting to avoid treatment (Delli et al. 2013). Providers must understand they are only reinforcing this behavior by allowing patients to avoid treatment, e.g., patient is experiencing a stimulus, reacting, and is rewarded when the undesired stimulus is removed. Introducing treatment in steps with desensitization visits can also help patients have a positive experience. The first time the patient comes to the office, the visit could simply consist of sitting in the waiting room.

From there, the patient may walk back to a treatment room. Patients continue to experience more each visit until the desired procedure is completed. Although this strategy can be effective, it is also very time consuming and may be difficult to implement in the private dental office. However, desensitization visits can be planned to minimize the amount of time spent on visits that are not truly benefiting the patient. When the first two visits just require visiting different parts of the office, appointments are quick and do not require significant time commitment for the dentist or office staff.

Given problems in relating and communication, it is important to realize that the frequent patterns of becoming overly polite when a person is having problem may be less helpful than direct instruction, e.g., instead of saying, "Please come sit in the chair so we can look at your teeth," the provider may have more success saying, "Sit here." Another way positive outcomes may be increased is by wearing a clear face shield instead of the traditional cloth facemask. Eye-tracking studies show that individuals with autism spend much more time focused on the mouth. Wearing a clear face shield allows individuals with autism to continue to gather information from the dentist's lower face throughout the procedure.

Staff should be aware of sensory overstimulation, e.g., the movement of the dental chair may cause anxiety, and this could be avoided by allowing the patient to stand while the chair reclines. Use of unscented/unflavored products can be helpful. minimize these obstacles. Applying dental products to a few teeth and quickly wiping away the excess as each tooth is cleaned can minimize sensation. "Paste-less" prophylactic angles can be extremely helpful when treating patients who cannot tolerate the sensation or taste of prophylactic paste in their mouth. If use of suction is a problem, gauze can be used to soak up saliva and water. The sound of the high-speed hand piece can also be distressing. When patients are having trouble tolerating bright light, dental mirrors with lights on the handle can be invaluable treatment tools.

Completing dental radiographs is a very important portion of the dental visit and is an essential part of the dental exam and diagnosis. Dental

radiographs provide information about the oral cavity that cannot be discerned any other way. Radiographs can be the deciding factor in determining whether or not a patient needs treatment in the operating room and how much operating room time will be needed. If radiographs cannot be completed, the dental provider must schedule extended operating room time for the patient in case the patient has extensive interproximal dental decay that cannot be visualized clinically. Many of the same strategies previously mentioned can be used in taking radiographs. It traditional bite-wing radiographs are impossible to complete, providers should consider attempting panoramic bitewings

Some papers report that the protective stabilizer (papoose) is used in as high as 44% of the time with children who have ASD. If providers are considering placing the child in a papoose, it should be discussed with parents at length before starting treatment. Every effort should be made to ensure the parent understands the purpose of the protective stabilizer and why it is used (9Eatonk 2005).

Pharmacological Treatment Aids

If other strategies are not successful, pharmacological management of behavior should be considered. There are many sedation protocols available for in-office treatment ranging from minimal to deep sedation. Services offered differ based on the provider's training, experience, and patient factors such as previous sedation experiences, health history, and current health status. In office, sedation is traditionally reserved for healthy patients with no medical complications. Outcomes of sedation procedures can be unpredictable even with the most experienced providers, and unpredictable and paradoxical reaction to some sedative agents have been noted (Volkmar and Wiesner 2009). If all other efforts fail, one option is generally anesthesia; treatment must be completed in the operating room under general anesthesia, and parents are often comfortable with this approach (Cuvo 2010). In such cases, consultation with the primary health care provider is important. The decision to treat a patient under general anesthesia should not be an

excuse to abandon intervention strategies that have been discussed to improve behavior at the dental visit. Behavior is less likely to improve over time in children with ASD than the general population, but improved behavior is possible with hard work. Dental providers and caregivers should continue to work towards successful completion of the dental visit in the office environment.

Future Directions

Regardless of caries rate experienced by the autistic population, all children are at risk for developing dental decay. For that reason, every child requires routine preventative dental care. When treating individuals with autism, it is important to remember that every patient will present with unique challenges and will respond differently to various intervention strategies (Delli et al. 2013). Providers must realize that an intervention strategy may be very effective for one patient and totally ineffective for another. Given the wide range in syndrome expression, clearly there is no single "cook book" to success when treating individuals with ASD.

Denver Development Screening Test (DDST)

Robin Hansen

Pediatrics, Center for Excellence in Developmental Disabilities, UC Davis
M.I.N.D. Institute, Sacramento, CA, USA

Synonyms

DDST; Denver II

Description

The Denver Developmental Screening Test, first published in 1967 (Frankenburg and Dodds 1967), was one of the first screening tools developed to identify young children at risk for developmental delay and disability. Its format was similar to the construction of pediatric growth charts, with 105 developmental items for children from birth to 6 years of age aligned chronologically along horizontal age lines, divided into four discrete developmental domains: personal-social, fine motor-adaptive, language, and gross motor. Bar graphs for each developmental item reflect the ages at which 25%, 50%, 75%, and 90% of typically developing children in the standardization sample completed the task. Because of criticisms related to low sensitivity in identifying children with speech and language delays, it was revised to add more language items, restandardized, and remarketed as the Denver II in 1992 (Frankenburg et al. 1992), retaining a similar format to the DDST. Both are administered by individuals who have trained to proficiency using training tapes/DVD or the administration manual, with standardized toys such as blocks, rattles, and pictures included in the toolkit. It is estimated to take 10–20 min to administer and score. Several options regarding item administration were developed and evaluated. The most commonly used approach in primary care settings included administering at least three items in each domain whose bar graphs are closest to but completely to the left

of the age line, indicating items that over 90% of typically developing children should be able to do by that age. Any of these items not successfully completed are considered a delay; items where the age line passes through the 75–90% section of the bar graph which the child cannot accomplish are scored “cautions,” and an algorithm for determining normal, abnormal (two or more delays), and questionable (two cautions or one delay) results is provided in the manual.

Historical Background

The DDST is most important for its historical background rather than as a currently recommended screening tool. It was the first developmental screening tool for young children that was widely marketed to the primary care medical community as well as child care providers and other child health professionals. It played a significant role in widespread recognition of the importance of early identification and intervention from a public health and primary care perspective. The role of parents as accurate observers of their children’s behaviors was also recognized by the developers of the DDST and subsequent screening materials such as the Denver Prescreening Developmental Questionnaire and the Denver II. The DDST and Denver II became widely used in the United States and internationally, being translated and restandardized in many countries.

Psychometric Data

The DDST was originally standardized on 1,036 children from Denver, age 1–72 months, with reported co-positivity scores of .92 and co-negativity scores of .99, using the Bayley Mental and Psychomotor Scales and Stanford-Binet Intelligence Scales as criterion tests. Subsequent studies of concurrent and predictive validity, reviewed by Meisels (1989), found that while the specificity remained high (.87–1.0), the sensitivity was unacceptably low (.13–.46),

particularly when children were reevaluated 14 months to 6 years later (.18). The Denver II was standardized on 2,096 children 0–6.5 years of age, half from Denver and half from rural Colorado. Inter-rater reliability and test-retest validity were reported to be .90 or greater (Frankenburg et al. 1992). Subsequent studies showed that, with these revisions, the Denver II had acceptable sensitivity of .83 reported by Glascoe et al. (1992), but specificity dropped to .43, shifting concerns about the DDST failing to identify children with significant delays to concerns about overreferral of typically developing children using the Denver II.

Clinical Uses

The Denver II is still marketed by Denver Developmental Materials Inc. However, it is not included in the most recent American Academy of Pediatrics guidelines for general developmental surveillance and screening as a recommended tool (2006) nor in the AAP guidelines for ASD screening (2007), as it has never been evaluated as a screening tool for ASD. Its format, however, continues to be useful for pediatric educators as a way of visually illustrating the importance of assessing different developmental domains simultaneously in individual children, of tracking development over time, and of showing the variability in ages at which different developmental items “typically” occur.

Deoxyribonucleic Acid

Paul El-Fishawy
State Laboratory, Child Study Center, Yale
University, New Haven, CT, USA

Synonyms

[DNA](#)

Definition

The instructions for the development and functioning of a living organism are contained in a molecule called deoxyribonucleic acid (DNA) which is a nucleic acid. The instructions are spelled out in a sequence or code of four chemical units called nucleobases (or bases for short). These are adenine, cytosine, guanine, and thymine, abbreviated as A, C, G and T, respectively. DNA is contained within nearly every cell of the human organism. Certain segments of the DNA

molecule called genes contain the code for creating the components of cells, most importantly, molecules called proteins (Alberts et al. 2002). James Watson and Francis Crick described the molecular structure of DNA in 1953 (Watson and Crick 1953).

DNA is passed from one generation to the next. In humans, the DNA molecule is divided up into a set of smaller pieces corresponding to chromosomes. Humans inherit 23 chromosomes from each parent, 22 of them are referred to as autosomes and are numbered 1–22 and one is called a sex chromosome and is either a chromosome X or a chromosome Y. Thus, normal human cells contain 44 autosomes and 2 sex chromosomes. The chromosomes are paired in each cell. For example, each cell will contain two copies of chromosome 1, one from the mother (the maternal chromosome) and one from the father (the paternal chromosome). Each of a pair of autosomes will generally contain the same genes. However, the sequence of DNA at each of the genes will often vary slightly between individuals, and it is also now clear that the structure of the chromosome, so-called copy number variations (CNVs), is also part of the normal complement of human genetic variation.

A change in the sequence or structure of DNA which results in a deviation from the agreed upon reference genome may be referred to in various ways, including an allele, a variant, a variation, a polymorphism, or a mutation. Typically, the word polymorphism is used when one is referring to a change that is present in a percentage of the population and mutation is taken to mean that the variation is rare and relates to a disease or phenotype.

Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA
Department of Pediatrics, Emory University, Atlanta, GA, USA

Synonyms

[Divalproex](#); [Valproic acid](#)

Indications

Valproic Acid: Valproic acid is a simple carbonic acid. It is available in several preparations including divalproex and valproic acid. It appears to exert its beneficial effects by interfering with the repetitive firing of neurons. This appears to be especially relevant for its treatment of seizures. Valproic acid is approved for the treatment of seizures, migraine, and for the treatment of bipolar disorder.

Clinical Use (Including Side Effects)

It has been studied in children and adults with bipolar illness and appears to be an effective treatment. Valproic acid is often well tolerated, but it can have a range of adverse effects. Sedation and gastrointestinal disturbance with vomiting are common particularly at the start of treatment. Other more significant adverse effects include thrombocytopenia, pancreatitis, and rarely hepatotoxicity. These more severe adverse effects require monitoring of drug level in the blood, platelet counts, amylase, and liver enzymes.

To date, valproic acid has not been well studied in children or adults with autism spectrum disorders. There are some open case studies suggesting benefit for aggression and agitation; however, these studies have not compared valproic acid to placebo.

Department of Vocational Rehabilitation

Oren Shtayermman
New York Institute of Technology Mental Health Counseling, Old Westbury, NY, USA

Synonyms

[Employment services](#); [Office of rehabilitation](#); [Vocational counseling](#)

Definition

The Department of Vocational Rehabilitation is a broad marker for an organization that provides services for persons identified with developmental disabilities (Rehabilitation Act of 1973, Public Law 93–112 93rd Congress, H. R. 8070 September 26, 1973). In the act, every state arranges a bureau of vocational rehabilitation services. In NY State, the office is frequently mentioned as VESID (VESID is an acronym for Vocational and Educational Services for Individuals with Disabilities).

In all states, the Department of Vocational Rehabilitation (DVR) delivers occupation services and treatment to those with disabilities who want to work but experience obstacles to work due to physical, sensory, and/or mental disability. A DVR therapist works with every person to develop an individually tailored strategy of services intended to aid them in reaching their employment goal. The aid may contain, but is not limited to, the following:

- Counseling and guidance
- Assessment services
- Independent living services
- Assistive technology services
- Training and education

Vocational and Educational Services for Individuals with Disabilities within the New York State Education Department has accountability criteria for meeting the needs of individuals diagnosed with disabilities from early infancy through old age, plus oversight of special education services for pupils with disabilities aged 3–21. Each year VESID offers thousands of New Yorkers who have a disability a chance to be independent through learning, preparation, and employment. In addition, VESID delivers vocational rehabilitation services to eligible individuals to prepare them for appropriate jobs. These jobs might be in the competitive work force, in private businesses, in supported employment on employer sites, or in sheltered shops. Moreover, VESID aids individuals with disabilities who are having trouble keeping their jobs. Offices of Vocational

Services throughout the country provide similar services and oversight.

Offices of Vocational Rehabilitation, or OVR, delivers vocational rehabilitation services to support persons with disabilities to prepare for, obtain, or maintain employment. The office also offers services to qualified persons diagnosed with disabilities, both directly and through a system of appropriate vendors. Services are provided on a personalized base. The therapist, through face-to-face interviews, helps clientele in choosing their choice of occupational goals, services, and service providers. An Individualized Plan for Employment (IPE) is established, charting a vocational objective, services, providers, and responsibilities. Some services are subject to a Financial Needs Test (FNT) and could involve fiscal contribution by the client. Counseling and guidance, diagnostic services, assessments, information and referral, job development and placement, and personal services such as readers or sign language interpreters are provided at no cost to the individual. Also, by law, OVR clientele awarded Social Security benefits for their disability (SSI, SSDI) are relieved from OVR's Financial Needs Test.

Types of Vocational Rehabilitation Services

The OVR runs a variety of services to qualified applicants. Certain services can aid in overcoming or lessening the disability; others can directly support and prepare for a vocation. The services will be organized to meet distinct needs.

The OVR services include:

Diagnostic services: Medical, psychological, and checkups and assessments used to improve understanding of the disability and needs for specific types of services.

Vocational evaluation: Ability, interest, overall ability, academic exams, work tolerance, and “hands-on” job experience used to understand vocational potential.

Counseling: Occupational therapy will help to better understand potential, to rely on abilities,

to set accurate vocational goals, to modify them once needed, to advance fruitful work ways, and to initiate a fulfilling career. Counseling is obtainable throughout rehabilitation program.

Training: Education to prepare for a job including, but not limited to, basic academic, vocational/technical, college, on-the-job training, independent living skills, and personal and work adjustment training.

Restoration services: Medical services and gear such as physical and occupational therapy, wheelchairs, and automobile hand controls can be provided to achieve employment.

Placement assistance: Counseling, job-seeking programs, job clubs, and job development used to upturn your skill to acquire a job.

Assistive technology: Assistive technology includes a wide range of devices and services that can empower individuals with disabilities to make the most of employment, independence, and integration into society. The office can help person with a disability in successfully choosing and obtaining appropriate assistive technology. They can arrange for an adviser to assess the situation and to make appropriate recommendations. The office also functions and maintains Center for Assistive and Rehabilitation Technology (CART) at the Hiram G. Andrews Center. There is no charge for evaluation and vocational counseling services through OVR.

Support services: Additional services are provided for eligible persons if they are essential to start and uphold occupation. Such services may include:

- Room, board, and transportation costs during an evaluation or while completing a rehabilitation program
- Occupational tools, licenses, or equipment
- Home modifications, adaptive or special household equipment; van or car modifications, including special driving devices or lifting devices
- Personal care assistance
- Job site modifications, independent living training
- Text telephone (TT), signaling devices, hearing aids, and interpreter services

- Specialized services such as rehabilitation teaching and orientation and mobility training for persons who are blind or visually impaired

Depressive Disorder

Betsey A. Benson and Whitney T. Brooks
Nisonger Center, UCEDD, The Ohio State
University, Columbus, OH, USA

Synonyms

[Depressive disorders](#); [Dysthymia](#); [Major depressive disorder](#); [Mood disorders](#)

Short Description or Definition

- Major depressive disorder
- Dysthymia
- Depressive disorders
- Mood disorders

Categorization

According to the DSM-IV-TR (American Psychiatric Association [APA] 2000), depressive disorders include major depressive disorder, dysthymic disorder, and depressive disorder not otherwise specified. Major depressive disorder includes the presence of a major depressive episode, with specifiers to indicate the severity and duration. Major depressive episodes involve symptoms that are present most of the day, nearly every day consisting of either depressed mood (can be irritability in children) or diminished interest or pleasure in activities, and at least four of the following: significant weight loss or weight gain, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue or loss of energy, feelings of worthlessness or excessive or inappropriate guilt, diminished ability to think or concentrate or indecisiveness, or recurrent thoughts of death, suicidal ideation without a plan, or a suicide attempt or specific plan for committing suicide. The symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning, and they must not be due to the direct effects of a general medical condition, a substance, a medication, or other treatment.

Dysthymic disorder includes the presence of depressed mood for most of the day, for more days than not, as indicated either by subjective account or observation by others, for at least 2 years (in children and adolescents, mood can be irritable, and duration must be at least 1 year) and at least two of the following: poor appetite or overeating, insomnia or hypersomnia, low energy or fatigue, low self-esteem, poor concentration or difficulty making decisions, or feelings of hopelessness.

Depressive disorder not otherwise specified includes disorders with depressive features that do not meet the criteria for major depressive disorder but present with subthreshold symptoms that cause clinically significant impairment or distress.

In the ICD-10 (WHO 1992), *depressive disorder* is defined by the presence of at least one depressive episode with the same key characteristics as in the DSM-IV-TR, such as lowering of

mood, decrease in activity, decrease in capacity for enjoyment, and difficulty in concentration. Somatic symptoms, such as marked tiredness, sleep, and appetite disturbance, are present, and ideas of guilt or worthlessness and suicidal thoughts are often present. Depressive disorders are also categorized by the severity and duration of symptoms, into mild, moderate, severe, recurrent, or with psychotic symptoms. The ICD-10 differs in the classification from DSM-IV-TR by its lack of a specific number of symptoms required to meet criteria.

Dysthymia in the ICD-10 is defined similarly as in the DSM-IV-TR, with chronic depression of mood that is not sufficiently severe or prolonged to justify a diagnosis of severe, moderate, or mild recurrent depressive disorder. However, the criteria do not specify a period of 2 years but rather indicates that the symptoms must last at least several years. *Other depressive disorders* include any other disorders that are not of sufficient severity or duration to meet criteria for depressive disorder or dysthymia.

(Note: Major depressive disorder, dysthymia, depressive disorder not otherwise specified, and other depressive disorders will be referred to collectively as “depressive disorders” or “depression” throughout.)

Epidemiology

The occurrence of depressive disorders in individuals with autism spectrum disorders is likely affected by the same complex genetic and environmental interactions seen in typically developing individuals (Ghaziuddin 2005). However, the impact of these factors is far less understood in ASD due to the lack of systematic epidemiological studies. Family studies suggest a genetic component to the presence of depressive disorders in ASD, with rates of major depression increased in first-degree relatives of individuals with autism and parents of children with ASD exhibiting higher risk for depressive disorders than parents of children with other developmental disabilities (Ghaziuddin and Greden 1998; Lainhart 1999). Families of individuals with ASD who present with depression at clinical settings have a history

of depression or suicide at a rate of 50–77% (Lainhart 1999). Stressful life events, including bereavement, peer victimization, and loneliness, could also contribute to the development of depressive symptoms in individuals with ASD (Ghaziuddin et al. 1995; Ghaziuddin 2005).

Despite the recognition that depressive disorders are relatively common in individuals with autism spectrum disorders, true prevalence rates are unknown because most studies have been conducted with psychiatric samples rather than population samples. However, these studies provide initial estimates of the rate of depressive disorders. Reviews of published research on co-occurring depressive disorders in ASD have reported a wide range of prevalence estimates, from 4% to 58% (Lainhart 1999; Lainhart and Folstein 1994; Stewart et al. 2006). The varied rates of depressive disorders in the literature likely reflect the heterogeneity of the samples and different methods of assessing depressive disorders. For example, the estimates differ depending on whether psychiatric or community samples were used, which ASD subtype was included, the age of participants, and whether psychiatric interviews or questionnaire assessment methods were used. Many researchers posit a higher rate of depressive disorders in ASD than in the general population and suggest that the disorders may be underdiagnosed (e.g., Ghaziuddin 2005; Lainhart and Folstein 1994).

In one of the first descriptions of children and adults with Asperger syndrome in a clinical setting, about one third of the adolescents (16 years and above) and young adults presented with clinical levels of depression (Wing 1981). Other reports describe depression as being the most common psychiatric disorder in Asperger syndrome, with 15% of adults referred to a psychiatric setting presenting with symptoms of depression (Tantum 1991). Despite the findings of several clinical studies and the recognition of the risk for developing depressive disorders in ASD, no population-based prevalence studies with adolescents and adults appear to have been completed.

There have been some promising studies examining the prevalence of depressive

symptoms in children with ASD, with larger, more representative samples. For example, a prevalence study of mood and anxiety symptoms among 9- to 13-year-old children with Asperger syndrome and high-functioning autism included a community standardization sample of 1,751 typically developing children (Kim et al. 2000). On a questionnaire of depression symptoms, 16.9% of the ASD sample scored at least two standard deviations above the population mean, suggesting a significantly higher rate of depressive symptoms than in the community sample (Kim et al. 2000).

An Australian study examined emotional and behavioral problems in 4- to 18-year-old children and adolescents diagnosed with ASD and with youngsters diagnosed with intellectual disability (learning disability) and no diagnosis of ASD (Brereton et al. 2006). The ASD group scored significantly higher on a measure of depression than the non-ASD group. Age and IQ in the ASD group also affected depression scores. Older children (13 years or older) scored significantly higher on the depression measure than the youngest age group (less than 6 years old), and those with higher IQs scored higher than individuals with intellectual disability (learning disability).

Standardized interview methods of assessment have been used infrequently in research on depression in ASD. Only one study was found to examine the prevalence rates of psychiatric disorders in a community-derived sample using a standardized interview measure (Simonoff et al. 2008). In this sample of children aged 10–14 years, a surprisingly low rate of depressive disorders (1.4%) was found.

When lifetime occurrence of depressive symptoms and a wider age range was included, a higher rate of depressive disorders was found. In a pilot study for the development of an ASD-specific psychiatric comorbidity interview conducted with 5- to 17-year-olds, 10% of a community sample with higher-functioning ASD met criteria for at least one major depressive disorder in their lifetime, and 25% met criteria for subsyndromal symptoms of depressive disorders (Leyfer et al. 2006).

The prevalence of depressive disorders in the general population varies by age with more

adolescents and adults presenting with depression than children (World Health Organization 2002). Research on depressive disorders in ASD suggests a similar pattern, with more adolescents and adults with ASD presenting with depression than children (e.g., Brereton et al. 2006; Martin et al. 2000; Simonoff et al. 2008). It is currently unknown if more women with ASD present with depression than men, as is the case in the general population (Ghaziuddin 2005).

Natural History, Prognostic Factors, and Outcomes

The presence of depressive symptoms in individuals with autism spectrum disorders was noted in the earliest descriptions of the disorders (Asperger 1944; Kanner 1943; Wing 1981). However, due to the lack of systematic population studies, the course of depressive disorders is not well understood.

Numerous publications have noted that the development of depressive disorders in adolescents and adults with Asperger syndrome and high-functioning autism in particular seems to be related to a developing awareness of “differentness” from their peers and unsuccessful attempts to establish friendships and romantic relationships (e.g., Ghaziuddin 2005; Howlin 1997; Wing 1981). The presence of depressive symptoms in children with Asperger syndrome and high-functioning autism has been found to be associated with higher rates of aggressive and oppositional behavior, along with poorer relationships with teachers, peers, and family members when compared to children with ASD without depressive symptoms (Kim et al. 2000).

In general, the outcomes for adults with autism spectrum disorders, with and without intellectual disability (learning disability), have not been promising, with decreased opportunities for employment, independent living, and access to community services (Howlin 2005). There is little information on the long-term outcome of persons with ASD and depressive disorders. However, clinicians report that the presence of co-occurring depressive disorders can result in

further impairment and disruption in functioning, such as increased morbidity and mortality, and a higher potential for drug interactions due to multiple pharmacotherapy treatment (Ghaziuddin 2005). Depressive illness can become chronic in some individuals, and a family history of mood disorders seems to be associated with a poorer treatment outcome (Ghaziuddin 2005).

Clinical Expression and Pathophysiology

The presentation of depressive symptoms in ASD shares many of the features seen in the general population, such as sadness and lack of interest in formerly pleasurable activities, but individuals with ASD may also present with unique features, due to their restricted range of emotional expression and difficulty in communication. While sad mood and loss of pleasure in activities are defining characteristics of depressive disorders, individuals with ASD are often referred to clinical settings because of changes observed by others, such as facial expressions of sadness or misery, or behavioral expressions, such as increased frequency of crying, irritability, or problem behavior (Stewart et al. 2006). Particular features that must be assessed carefully in individuals with ASD include an increase in social withdrawal, changes in the character of stereotypic and repetitive behavior, and restricted interests, irritability, and regression of skills (Ghaziuddin 2005).

Other factors that are likely to affect the presentation of depressive disorders in ASD include age, gender, cognitive and verbal ability, other psychiatric disorders, and other medical disorders. Younger children may be more likely to present with irritability than with sad or depressed mood, and this is recognized in the DSM-IV-TR criteria, which allows for substitution of irritability for depressed mood in children (APA 2000). Research suggests an increase in depressive symptoms with age (e.g., Brereton et al. 2006). The risk of depression and other psychiatric disorders may be higher in individuals with Asperger syndrome and higher-functioning individuals with autism because their relatively good cognitive and language skills may lead others to

overestimate their abilities and put more pressure on them to “fit in” with peers, while overlooking the severe difficulty they have in understanding social interaction. However, there is not enough evidence at this time to make any conclusions about differential risks of developing depression in these groups (Howlin 2005).

Individuals with Asperger syndrome and higher-functioning autism may present with depressive symptoms differently than individuals with autistic disorder. They may be able to verbally describe feelings of sadness and loneliness, while individuals with more cognitive impairments may not be able to express themselves verbally and may present with more behavioral signs, such as irritability, aggression, and changes in sleep and appetite. However, it is important to recognize that individuals with higher-functioning presentations of ASD and intact language abilities may not be able to accurately describe their emotions and may present with atypical signs and symptoms of depressive disorders, such as irritability or bizarre ideation (Howlin 2005).

The presence of other psychiatric disorders can also affect the presentation of depressive symptoms. The co-occurrence of mood and anxiety disorders is common in the general population, and research suggests that these disorders often co-occur in people with ASD (e.g., Lainhart 1999). The presence of symptoms associated with anxiety, such as increased stereotypic behaviors, may make it more difficult to assess depressive disorders in individuals with ASD.

Evaluation and Differential Diagnosis

The classification of psychiatric disorders in ASD has involved considerable controversy. Many early researchers adopted a hierarchical approach to diagnosis and argued that psychiatric disorders could not occur in individuals with intellectual disability (learning disability) or autism spectrum disorders. A hierarchical approach conceptualizes symptoms that overlap with other disorders as part of the primary disorder, with little room for the diagnosis of co-occurring psychiatric disorders.

An alternative diagnostic approach to the hierarchical approach classifies all symptom constellations that meet criteria for a particular disorder and allows for identification of multiple disorders (Simonoff et al. 2008). Despite the controversy in the literature, many now agree that the full spectrum of psychiatric disorders can co-occur in ASDs (Ghaziuddin 2005; Matson and Nebel-Schwalm 2007; Simonoff et al. 2008).

Despite the recognition that depressive disorders can and do occur in ASD, diagnosing them in individuals with autism spectrum disorders can be particularly difficult due to a variety of factors, including an overlap between symptoms of depressive disorders and features of ASD, such as poor eye contact, restricted affect, and lack of voice inflection. For example, it may be difficult to determine whether the social withdrawal observed in an individual with autism is part of the core social deficits of autism spectrum disorders or is symptomatic of a co-occurring mood disturbance.

An important factor in making an accurate diagnosis of depressive disorders in ASD is having reliable information from multiple sources. If the individual with ASD is able to provide information about symptoms, it is important to assess these carefully. However, given the difficulties that individuals with ASD have in expressing and understanding emotions, it is also important to obtain information from caregivers, teachers, and family members about typical patterns of behavior. Reports by others may also be helpful to interpret self-report of individuals with ASD. The clinician needs to obtain a detailed picture of the individual's baseline levels of social activity, interests, restricted and repetitive behavior, maladaptive behavior, and adaptive skills, in order to detect distinct differences in these areas that may indicate the onset of mood disturbance. Information obtained from parental report concerning developmental and social history, including the presence of significant life events, and the results from prior assessments, such as medical and psychological evaluations, intelligence, and adaptive behavior testing, can complete the diagnostic picture. A detailed physical examination is recommended to rule out other possible causes

of depressive symptoms such as thyroid disorders (Ghaziuddin 2005).

Intellectual disability (learning disability) commonly co-occurs in ASD, with estimates of 30–70% of individuals with ASD functioning in the ID (LD) range (Fombonne 2005). The presence of ID (LD) in this population has important implications for how depression is assessed in this heterogeneous group. The diagnostic manual for intellectual disability (DM-ID) proposed adaptations to the DSM diagnostic criteria for persons with intellectual disabilities based on clinical consensus (Fletcher et al. 2007). The DM-ID includes irritable mood as an acceptable substitute for depressed mood for people with ID which the DSM-IV-TR includes in the criteria for children (APA 2000). The DM-ID reduces the number of symptoms by one for diagnosing major depressive disorder, requiring four symptoms instead of five if the individual has limited expressive language skills. The other important adaptation is that the DM-ID allows observer report for many symptoms (Charlot et al. 2007). This practice is compatible with clinical reports concerning individuals with ASD in which most cases of depression are brought to clinical attention by observations from caregivers rather than by self-report of the individual.

While the alternative diagnostic criteria put forth in the DM-ID represent an important step in the understanding of co-occurring psychiatric disorders in individuals with all types of developmental disabilities, there remains a lack of ASD-specific psychopathology assessment methods. Many studies on depression in ASD have relied on scales or structured interviews designed for the general population or for individuals with intellectual disability. Consequently, it is difficult to determine if these measures are sensitive to the characteristic features of ASD.

A semistructured psychiatric interview was developed to assess psychiatric disorders in children and adolescents with ASD (Leyfer et al. 2006). The Autism Comorbidity Interview – Present and Lifetime Version (ACI-PL) was modified from the Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS, Chambers et al. 1985). This measure aims to distinguish the core

symptoms of ASD from symptoms of comorbid psychiatric disorders. It demonstrated good reliability and validity, although the validation sample was limited to individuals with higher-functioning ASD.

The further development of ASD-specific screening measures and structured diagnostic interviews is important to improve the accurate identification of depressive disorders in ASD and to gain access to specific, effective treatment.

Treatment

The treatment of depressive disorders in individuals with ASDs is largely pharmacological in nature, with antidepressant medication being prescribed most often and selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, sertraline, and fluvoxamine, showing the greatest success in symptom reduction (Lainhart 1999; Stewart et al. 2006). It is difficult to determine if psychopharmacological treatments are being used in this population specifically to treat depressive disorders because a large percentage (30.5%) of individuals with ASD take one or more psychotropic medications (Aman et al. 1995). Antidepressants may be prescribed for repetitive or compulsive behavior as well as for depressive symptoms. A naturalistic study, which examined psychotropic drug use among a sample of 109 individuals with high-functioning ASD, reported that about a third of the participants were prescribed an antidepressant with about one fourth taking an SSRI (Martin et al. 2000). Depression was identified as the reason for taking psychotropic medication in about 30% of participants. The response to antidepressants by patients with ASD is reported to be similar to the general population (Ghaziuddin 2005). Side effects, if they are problematic, tend to be related to other medical issues such as seizures.

There is increasing recognition that cognitive behavior therapy may be an effective treatment for psychiatric disorders in individuals with Asperger syndrome (Anderson and Morris 2006; Attwood 2003). Cognitive behavior therapy for depression has been used with individuals with Asperger

syndrome with resulting improvement (Hare 1997). Depending on the individual's level of functioning and communication abilities, CBT may be an appropriate treatment choice. Further study is needed to determine the effectiveness of CBT with individuals with ASD and to identify the active components of the treatment.

Social skills training, environmental modifications, and behavioral interventions may have a role in addressing depressive symptoms in individuals with ASD. Psychosocial interventions are often used in conjunction with medications to treat depressive disorders.

Dermatoglyphic Patterns

Jessica L. Roesser

Department of Pediatrics (SMD), University of Rochester, School of Medicine and Dentistry, Rochester, NY, USA

Definition

Dermatoglyphics refers to the study of fingerprints and handprints. Dermatoglyphic patterns are the unique ridges and whorls of the skin of the fingertips and palms. Each individual person (even genetically identical twins) has a slightly different pattern of ridges and whorls on the fingers, especially the tips and palms. There can be unique patterns of the lines that cross the palms and fingers as well. The creases of the palms may be altered in specific genetic syndromes. The dermatoglyphic pattern of the fingerprint is determined prenatally. At this point, the literature on dermatoglyphic patterns in children with ASD is conflicting. The evidence does not indicate that there are differences in the ridges/whorls or palm prints of children with autism spectrum disorders, although there may be differences related to associated or underlying genetic disorders.

Definition

Systematic desensitization refers to the therapeutic technique of gradually exposing an individual to increasingly difficult anxiety-producing conditions in an effort to help an individual reduce anxious responses in those situations by adopting more adaptive ways of coping. The closely related process of counterconditioning consists of coupling opposing, positive responses (e.g., relaxation) to situations known to cause fear or anxiety. By substituting a new, adaptive response to fearful settings, the individual learns to elicit a more appropriate reaction in fearful situations. The development of a hierarchy of fearful conditions (i.e., consists of identifying a range of situations from least to most anxiety provoking) plays a key role in this intervention by serving as a framework for gradual exposure. Anxiety-related situations are introduced in a step-by-step process beginning with the least challenging and progressing to the more difficult. This technique has been used effectively with children and adults with autism.

Historical Background

Systematic desensitization originates from classical conditioning theory. In 1920, John B. Watson demonstrated that fearful responses could be conditioned. Watson conditioned a fear of rats in an infant, referred to as “Little Albert,” by pairing the presence of a white rat with a sudden loud noise (Watson and Rayner 1920). Eventually the presence of the rat by itself elicited a fear response that generalized to all furry objects. Watson postulated that emotional responses could be learned and modified to generalize to a broader category of stimuli. The seminal work by Watson laid forth evidence for the development of phobias.

In response, Mary Carver Jones conducted instrumental research examining the mechanisms in which fearful responses could be reduced and generalization of these new responses achieved (Jones 1924). She treated a young boy, “Peter,” whom she selected partially because of characteristics (i.e., fear of white rats and other furry animals and objects) he shared with “Little Albert.” In the experiment, Peter was gradually presented with increasingly difficult fearful situations while he was simultaneously engaged in a pleasant activity. Initially the rabbit was presented a considerable distance away, and over a period of multiple sessions, it was gradually moved closer to Peter. During each of these sessions, Peter received his favorite food that was presented to him by a friendly peer or adult in the presence of the rabbit (Lang 1966). Peter initially demonstrated fearful responses to the rabbit but gradually exhibited that he was comfortable by holding the rabbit on his lap and he ultimately showed affection towards it. Through the process of gradual exposure, coupled with positive reinforcement (both through tangible rewards and social praise), Jones effectively demonstrated mechanisms through which fear could be reduced.

Building on the findings of Mary Carver Jones, Joseph Wolpe developed and operationalized the method of systematic desensitization to treat clients with anxiety and phobias, especially those connected to situations in which no real danger was present (Wolpe 1958). He based his method on the principle of reciprocal inhibition, which

emphasized that opposite responses to anxiety, such as relaxation, could be utilized to diminish anxiety. Though Wolpe acknowledged that other responses also compete with anxiety (Wolpe 1990a), he incorporated relaxation as the “reciprocally inhibiting” response in his treatment through gradual exposure. Wolpe’s seminal research on systematic desensitization provided a theoretical explanation for the success of gradual approaches through which the therapist determines the degree to which a patient is exposed to anxiety-provoking stimuli (Wolpe 1961). He also developed the method of imagery construction within systematic desensitization (having the client imagine fearful situations) to gradually expose clients to anxiety-provoking scenarios without confronting them directly to begin with. Systematic desensitization was reportedly successful for treating anxiety of nonpersonal stimuli (enclosed spaces, harmless animals, etc.) as well as interpersonal stimuli (fears of specific people or fear of being criticized). Also, Wolpe’s method treated fears that could not be brought into a therapist’s office such as complex social situations in a community setting (Lang 1966). Overall, the method adequately treated abstract fears and anxieties, which separated systematic desensitization from other treatments available at the time.

While Wolpe originally incorporated imagined exposures during treatment, many clinicians now use *in vivo* exposures when implementing systematic desensitization. These *in vivo* exposures involve direct exposure to the actual fear-inducing stimuli. Both imagined exposure and *in vivo* exposure produce diminished anxiety levels in patients. With children, *in vivo* exposure tends to be used more.

Rationale or Underlying Theory

Wolpe hypothesized that the underlying process at work during systematic desensitization is reciprocal inhibition. If a client can be taught to elicit a response oppositional to anxiety (e.g., relaxation) while in the presence of anxiety-evoking stimuli, then the anxiety response weakens eventually leading to diminished or no anxiety (Wolpe

1958). Pairing such a response with systematic presentations of increasingly anxiety-provoking stimuli, fear responses gradually diminish even in response to the most fearful situations.

The theory of habituation provides another explanation for the changes that occur during systematic desensitization (Antony and Stein 2008; Watts 1971). The longer and more often a client is exposed to anxiety-producing stimulus, the less effect that stimulus is presumed to have. When a person is exposed to anxiety-producing stimuli without negative consequences (e.g., petting a dog without getting bitten), negative thoughts are challenged and new, more adaptive information is encoded (Antony and Stein 2008). As a client spends more time exposed to these situations free from negative consequences, the person becomes “habituated” to the stimuli and previously distressing situations no longer cause unmanageable levels of anxiety.

Modern theorists also incorporate cognitive approaches to explain the success of systematic desensitization in treating anxiety symptoms. A retrieval competition theory posits that when clients are exposed to feared stimuli with no negative consequences, they begin to form different mental representations of these situations. Positive aspects of the exposure such as free choice, relative safety, and perceived self-efficacy all contribute to the formation of new mental representations (Brewin 2006). As exposures are repeatedly completed, these more positive representations are primed for retrieval and activated more quickly than the original negative representations.

Goals and Objectives

The overall goal of systematic desensitization is to reduce anxiety in feared situations. The method aims at addressing fears and anxieties through gradual exposures. Systematic desensitization can be used to treat a range of anxiety symptoms, particularly phobias, from the specific (e.g., fear of snakes) to the abstract (e.g., fear of embarrassment). In this way, phobias such as fear of crowds or fear of public speaking can be remediated in behavioral therapy. While some models of the

method utilize only imagined exposure and others incorporate exposure in naturalistic contexts, the objective is to gradually weaken anxious responses to anxiety-evoking stimuli and to minimize the probability of fears returning after being successfully treated (Brewin 2006). Modern research suggests that the “return of fear” phenomenon is most likely to occur when exposure therapy is conducted only in limited contexts (e.g., clinics), rather than also in the naturalistic settings where fear is experienced in everyday life (Mineka et al. 1999; Mystkowski et al. 2003).

Treatment Participants

Systematic desensitization is appropriate to treat phobias or anxiety symptoms in both children and adults. Given that phobias and anxiety present themselves in a range of populations, the process has been effective in treating a variety of conditions (Brooks et al. 2007; Davis et al. 2011; Frank et al. 1988; Morrow 1986). Research indicates particular effectiveness in treating specific phobias (Gelder et al. 1967), such as with snakes (Lang and Lazovik 1963) or claustrophobia (Wolpe 1961). Systematic desensitization has also proven effective to treat fears and anxieties in persons with cognitive limitations (Erfanian and Miltenberger 1990) and autism spectrum disorders (ASD) (Jackson and King 1982; Koegel et al. 2004; Luiselli 1978; Luscre and Center 1996; Wood et al. 2009).

Systematic Desensitization and Autism Spectrum Disorders

Individuals with ASD often experience symptoms of fear and anxiety (Gillot et al. 2001; White et al. 2009). Many systematic desensitization interventions among children with autism involve in vivo exposures within the actual setting (Koegel et al. 2004; Luiselli 1978; Luscre and Center 1996; Wood et al. 2009). Luiselli (1978) used in vivo systematic desensitization to successfully treat a child with autism who feared riding the school bus. Additionally, systematic desensitization significantly reduced fear of dental visits in children with autism (Luscre and Center 1996), and in

another study, it was used to successfully eliminate fearful behaviors to common auditory stimuli (e.g., sounds from a vacuum, flushing toilets) in three children with autism (Koegel et al. 2004).

Wood et al. (2009) incorporated systematic desensitization as a component of their cognitive behavioral therapy. Children with autism moved through individually designed fear hierarchies in which they were presented with in vivo exposures and received a variety of reinforcers for their participation. Immediately before and immediately following each exposure, a therapist guided the client through conversations aimed at restructuring negative thoughts with more adaptive cognition. Case studies of this treatment are given in Sze and Wood (2007, 2008), with anxiety targets ranging from intrusive thoughts (worries and obsessions) to separation anxiety, social avoidance at school, and compulsive behaviors.

These studies suggest that systematic desensitization is effective in treating anxious responses in children with ASD.

Treatment Procedures

Joseph Wolpe’s original treatment paradigm remains at the foundation of systematic desensitization while some elements have been modified. For example, current systematic desensitization procedures now employ more in vivo exposure rather than imagined exposure when possible. In fact, Wolpe himself utilized in vivo exposures when imagined exposure did not effectively treat a patient’s symptoms (Wolpe 1990a). Similarly, though relaxation is used as a means of reciprocal inhibition (Graziano and Kean 1968), other methods have been used as well such as positive reinforcement (Koegel et al. 2004; Luiselli 1978; Wood et al. 2009) and laughter (Jackson and King 1982). All systematic desensitization treatments continue to function on the principles of reciprocal inhibition and/or habituation.

Before implementing an intervention using systematic desensitization, a hierarchy of fears is established. This hierarchy refers to a list of various situations ordered from mildly to severely anxiety provoking (e.g., Wood and McLeod

2008). For example, a mild anxiety-inducing situation in a patient with a fear of snakes would be imagining a snake lying on the ground, while a severe anxiety-provoking situation would be holding a small, defanged, nonpoisonous snake. The hierarchy delineates the full range of conditions that produce fear. The items on the hierarchy can be conceptualized as steps or levels that range from a continuum from least to most anxiety provoking. It is developed before implementing treatment because it serves as a guideline for treatment goals (Lang 1966). Treatment proceeds in a step-wise progression beginning with mild anxiety-producing situations and gradually addresses more severe anxiety-producing scenarios on the hierarchy. The patient should exhibit and report diminished levels of anxiety before moving to the next step in the hierarchy. Employing a hierarchy during treatment has shown to increase the effects of systematic desensitization (Morrow 1986) and has been a constant component of systematic desensitization since Wolpe first described the treatment.

Incorporating relaxation into systematic desensitization treatment produces substantial effects (Wolpe 1958). The presence of a relaxation response inhibits anxiety or fear arousal because it is inherently antagonistic to both (Lomont and Edwards 1966). However, some research indicates that relaxation training is an unnecessary component to treatment (Agras et al. 1971). While the degree of focus on relaxation may vary, many systematic desensitization treatments continue to include it as a component. Given that it requires intensive focus, relaxation training in children may be challenging (King et al. 1990), especially in children with mental retardation or low-functioning autism (Graziano and Kean 1968). To circumvent these challenges, immediate positive reinforcement (praise, edibles, toys, etc.) may substitute as an adequate means of attaining reciprocal inhibition and has been successful in treating anxiety in children with ASD (e.g., Wood et al. 2009). This type of treatment paradigm often occurs when employing in vivo exposures rather than imagined exposures. Luiselli (1978) used verbal praise and edible treats for each successive step a child completed in riding the school bus. In

a study of hypersensitivity to auditory stimuli in children with autism (Koegel et al. 2004), children's favorite snacks and verbal praise were used to reinforce the children during in vivo exposures. Similarly, Luscre and Center (1996) employed individualized rewards (i.e., music, Play-Doh, fruit, etc.) during and after exposures. Jackson and King (1982) found that laughter could be used as an effective means of inhibiting anxiety in a child with autism suffering from a phobia of the sound from flushing toilets. These studies indicate that the effectiveness of systematic desensitization in children with autism may be enhanced when positive reinforcement or pleasant experiences are coupled with anxiety-provoking situations.

Efficacy Information

The efficacy of systematic desensitization is well documented (Chambless et al. 1998; Choy et al. 2007; Wood et al. 2009). Since the treatment requires individualization to the patient, there are numerous single-case studies published (e.g., MacDonald 1975; Sze and Wood 2007, 2008). However, studies have also emphasized the effectiveness of systematic desensitization in larger sample sizes (e.g., Frank et al. 1988; Wood et al. 2009). The degree of efficacy varies and is associated with the type of phobia, the severity of symptoms, the length of intervention, as well as individual attributes (e.g., treatment motivation) that is evidenced across typically developing populations (Wolpe 1990b) and children with ASD (Koegel et al. 2004; Sze and Wood 2007, 2008). Despite these variations, it seems that systematic desensitization is generally an effective treatment method in treating anxious responses in ASD.

Outcome Measurement

Abstract concepts such as "fear" and "anxiety" can be difficult to measure. As a result, outcome measurement varies across studies. One common method is to measure outcome by the number of

steps completed in a fear hierarchy. Many single-case methodological studies utilize this approach as a means of determining the success of treatment in ASD (Koegel et al. 2004; Luscre and Center 1996). Additionally, the occurrence of anxious behavioral responses (e.g., crying, running away) has been measured using frequency counts or calculated as percentages of occurrence within specific timed intervals using direct observation or review of videotaped sessions (Koegel et al. 2004).

Other measures include parent or patient report of anxiety symptoms (Kendall 1994; Wood et al. 2009). These self-report measures are subjective ratings (King et al. 1990) and are often used in conjunction with other measures. In order to limit subjectivity, reports may be recorded using standardized anxiety scales such as subjective units of distress scale, which is a 0–100-point scale usually administered with adults to assess their subjective anxiety levels (Choy et al. 2007). When children are the subjects of treatment, measures of parent report are often obtained.

Since changes in physical (somatic) responses such as increased respiration, cardiac rate, blood pressure, or galvanic skin response (GSR) serve as indicators of fear or anxiety, physiological measures may also be recorded as a means of indicating anxiety (Fisher et al. 2009). All of these outcome measurements are intended to determine the remittance of anxiety behaviors.

Qualifications of Treatment Providers

Trained clinicians familiar with behavioral principles and the treatment population have implemented systematic desensitization. Understanding the rationale of the treatment likely increases the effectiveness of how the treatment is delivered. While therapists typically deliver the treatment, there are resources available for parents, teachers, and even patients themselves to learn to implement the treatment (Merrell 2001); however, the efficacy of such implementation has yet to be determined.

Definition

Desipramine is a tricyclic antidepressant. The term tricyclic refers to the three-ring structure of this class of antidepressant medications. These medications are not used as commonly as in the past as they have been largely replaced by the SSRIs. Desipramine has been used to treat depression and attention deficit/hyperactivity disorder. Desipramine has highly selective norepinephrine reuptake inhibitor properties.

The tricyclic antidepressants have several adverse effects in common including dry mouth, urinary retention, constipation, nausea, increased heart rate, dizziness, and, at higher doses, confusion. The tricyclic antidepressants also carry some risk of altering the electrical conduction in the heart. They are well known to be fatal on overdose due to their potential for causing cardiac arrhythmia. Because of their known toxicity at higher doses, treatment with tricyclic antidepressants requires blood-level monitoring and electrocardiogram monitoring as well. Finally, the tricyclic antidepressants are also vulnerable to drug-drug interaction. For example, some medications such as SSRIs or certain antibiotics may interfere with the breakdown of tricyclic antidepressant medications. The interference of metabolism of the tricyclic can cause a sharp increase in the blood levels

of the tricyclic antidepressants and increase the vulnerability to toxic effects. The tricyclic medications have not been well studied in children or adults with autism.

Detection of Autism by Infant Sociability Interview

Dawn Wimpory

School of Psychology, University of Wales Bangor, Gwynedd, UK

Synonyms

[DAISI](#)

Description

DAISI is a semistructured detailed developmental history interview designed to elucidate a child's early sociability and communication. It is for concurrent or retrospective use with parents in clinical and research investigations, particularly those concerning autism. Wimpory, Williams, Nash, and Hobson (2000) provides

details of DAISI with an appendix clarifying its schedule and criteria for positive and negative responses, as scored from verbatim parental responses.

The instrument focuses on developmental progression in the manifestation of social engagement in young preschool children with autism through a semistructured interview drawing out retrospective reports of social engagement from their parents. It employs a conversational style masking when the interviewer moves from one to another of DAISI's 19 items. The interview is designed to facilitate the development of a relationship between parent(s) and interviewer so that honest/accurate replies are more likely. To this end, DAISI involves sensitive probing with situational prompts. Questions are ordered to increase the likelihood that parents will be able to give an initial positive response before having to describe any negative responses on further detailed questioning. Rather than focusing merely on discrete communicative skills, there is a focus on the infant's role in any interactive flow of preverbal engagement.

The interview schedule is reproduced below from an appendix within a paper by Wimpory et al. (2000) documenting DAISI's initial published use. DAISI can take up to an hour to administer and requires an understanding of typical and autistic early social communication rather than specific training. Although it was originally designed clinical psychologists' use for clinical and research purposes, it has subsequently been successfully employed by a range of professionals and researchers.

Wimpory et al. (2000) retrospectively used of DAISI with twenty 2–4-year-olds, prior to any autism diagnoses being made, found 15 key items differentiating the children who were subsequently diagnosed with autism from those with nonautistic developmental delay. Distinguishing items include engaging in dyadic social interaction (i.e., sociability in play with or without toys, socially directing feelings of anger and distress, frequency and intensity of eye contact, greeting parents, waving, raising arms to be picked up, enjoying lap games, preverbal turn-taking, and

using noises communicatively) as well as “triadic” social behavior, involving an object and another person (i.e., referential eye contact, pointing and following others' points, offering and giving, and showing objects).

The evidence from the study by Wimpory et al. (2000) indicated that infants with autism manifest a range of abnormalities suggestive of profound limitations in social engagement. These abnormalities were specific to the group with autism and were *not* simply an expression of general developmental delays because they were not characteristic of the infancies of children in the matched control group. Moreover, the abnormalities were *both* in the area of person-to-person nonverbal communication and interpersonal contact *and* in triadic person-person-object interactions. In the former respect, it is notable that the abnormalities extended to socially directed expressions of anger and distress as well as signs of positive engagement. In the latter respect, there were a majority of infants without autism but *no* infants with autism who were reported to offer, give, show, or point to objects in relation to someone else. Finally, nearly all of the infants in the control group, but not a single child with autism, were said to have followed another person's point.

These findings are in keeping with autism theories that focus on impairments in primary intersubjectivity as well as recognize the importance of difficulties with secondary intersubjectivity (Hobson 1993; Newson 1984; Rogers and Pennington 1991; Wimpory et al. 2002). Concurrent use of the 15 key DAISI items that Wimpory et al. (2000) found to be significant also determined significant group differences between the infant siblings of autistic spectrum disordered (ASD) and typically developing children as detailed below (Stone et al. 2007). Stone et al. (2007) also found significant correlation between total scores from the DAISI and a direct child measure of social-communicative functioning, The Screening Tool for Autism in 2-Year-Olds.

Findings from Wimpory et al.'s use of DAISI, along those from other studies, determined 25 key items for Dereu et al. in screening for ASDs (Dereu et al. 2010). They successfully evaluated

the Checklist for Early Signs of Developmental Disorders (CESDD) in a population of almost seven thousand 3–39-month-olds. In summary, DAISI has been used for research retrospectively, with children who have autism or non-autistic developmental delay and concurrently with infant siblings of children with autistic spectrum disorders (ASD) and typical development. It has also been employed for diagnostic purposes in clinical/educational settings for two decades.

Historical Background

DAISI's development was influenced by child clinical training at Nottingham University's Child Development Research Unit, and particularly by Professor Elizabeth Newson's guidelines (1990). The originality of data published on DAISI, by Wimpory et al. (2000) lies in the fact that the interview was carried out before any diagnosis was made; so the parents did not have any *a priori* assumption when recounting their child's social behavior.

In this respect, the DAISI differs from earlier questionnaires that were used with parents of affected children or adults, such as Dahlgren and Gillberg (1989) and Wing (1969). The latter were completed after the diagnosis of autism had been made and after years of experience of the person with autism, which might have influenced the results. Also, despite the fact that questionnaires are concise and easy to use, they are less sensitive than interviews and provide less accurate answers. These methodological limitations were a feature of almost all previous studies of this kind, even if the period recalled was not so distant. The DAISI interview is designed to give the impression of a natural conversation. There are opportunities for explanation, discussion, and provision of examples as part of the interchange. While previously published diagnostic instruments for young children with autism, such as the Parent Interview for Autism (PIA; Stone and Hogan 1993) and the revised Autism Diagnostic Interview (ADI-R; Lord et al. 1993), record impairments in social relatedness, they do not focus exclusively on

early social engagement in young preschool children.

The DAISI interview was developed to overcome several of the methodological issues that were a feature of previous research involving retrospective parental accounts. For example, it focuses on aspects of social engagement that are prominent in the behavior of typically developing infants and thus identify what may be abnormal in the case of autism. In addition, interviewing parents of young children with a specific focus on the first 2 years of life means that recall is required over a relatively short period (e.g., over 6–24 months in Wimpory et al. 2000).

Psychometric Data

The internal consistency of the DAISI was determined using the Kuder-Richardson-20-statistic (for dichotomous data) on retrospective use of DAISI with parents of twenty 2–4-year-olds, prior to any autism diagnoses (Wimpory 1995). This gave a standardized item alpha coefficient of 0.9. Significant autistic versus developmentally delayed nonautistic group differences emerged from analysis of variance on the total DAISI scores, $F(1,18) = 166.94, p < .0001$.

As indicated above, Wimpory et al. (2000) reported 15 key items that differentiated the infancies of children subsequently diagnosed with autism (mean score = 3.6, SD 2.4, range 0–7) from those with nonautistic developmental delay (mean score = 15.7, SD 2.5, range 13–19; Mann-Whitney $U = 0, p < .0001$). Distinguishing items, computed on an item by item basis (with Fisher's exact one-tailed test), indicated impairments in frequency/intensity of eye contact ($p < .0001^*$) and its referential use ($p < .0001^*$); pointing ($p < .0001^*$) and following others' points ($p < .0001^*$); using noises communicatively ($p < .0001^*$); preverbal turn-taking ($p < .0004^*$); raising arms to be picked up ($p < .0004^*$); offering and giving ($p < .0004^*$); greeting ($p < .005$); showing objects ($p < .005$); sociability during play with toys ($p < .005$); socially directing anger/distress ($p < .010$); sociability during play

without toys ($p < .016$); waving appropriately ($p < .016$); and enjoying lap games ($p < .043$). Asterisks indicate specific items that individually discriminated between the autistic and developmentally delayed nonautistic groups, following stringent Bonferroni correction for multiple comparisons.

For the above retrospective research, DAISI total scores correlated significantly with Childhood Autism Rating Scales (CARS) scores for the entire group ($-.891, p < .0001$; Wimpory 1995). For the subgroup with developmental delay, DAISI total scores and CARS scores showed a significant negative correlation (Spearman rank correlation $-.86, p = .001$); this was not significant for the group with autism (Spearman rank correlation $-.02, ns$; Wimpory et al. 2000). Within each group, there was a relatively small range of DAISI total scores. The significant negative correlation in the case of control (nonautistic developmentally delayed) individuals is of note because here the individuals who were reported to show a number of social deficits on the DAISI (and thus achieved lower scores) were also those who were given relatively high scores for abnormality on the CARS.

Stone et al. (2007) concurrently employed the 15 key DAISI items that the retrospective study by Wimpory et al. had found significant (2000). Stone et al. (2007) reported significant group differences between infant siblings of 64 autistic spectrum disordered and 42 typically developing (TD) children (MD, 1.32; 95% CI, 0.27–2.37). Autistic siblings' mean scores were 12.8 (SD 3.2, range 0–15), while TD siblings' mean scores were 14.4 (SD 1.2, range 10–15). Stone et al. (2007) also found that DAISI total scores correlated significantly with:

1. CARS total scores (0.74, $p < .01$)
2. Mullen Scales of Early Learning subscores (The Early Learning Composite; Visual Reception, Expressive and Receptive Language; 0.46; 0.28; 0.41; 0.39, respectively, all at $p < .01$)
3. Screening Tool for Autism in 2-Year-Olds total scores (STAT; $-0.37, p < .01$).

This last finding supports face validity for the DAISI as a parental report measure for broadly similar child social-communication constructs that are directly assessed by the STAT.

Clinical Uses

The DAISI interview was designed for both clinical as well as research purposes. It has been employed for multi-agency clinical/educational diagnostic purposes in some services in England and Wales for over two decades. The expanded clinical form includes items assessing the triad of autistic impairments during both early and current functioning, while the published form focuses exclusively on aspects of sociability and communication in infancy. Parental responses are recorded verbatim, and each item that corresponds to a specific domain of behavior is scored as present or absent as indicated above, the interview relies on the relationship between the interviewer and the parent so that accurate and honest answers are more likely to be provided. DAISI's clinical advantage over standardized diagnostic interviews is that it can be administered much more quickly and affords a more conversational experience, so assisting the clinician in gaining a good rapport with clients within routine diagnostic assessments.

The DAISI Schedule

The following section identifies the specific domains of functioning assessed using the DAISI. Each domain contains a key question (italicized in bold below) and may also have associated questions. These are designed to elicit a comprehensive description of behavior relevant for the domain under consideration. The key questions, identified by corresponding item numbers, are those used to determine DAISI scores, as outlined below. These key questions may be substituted by and/or preceded and/or followed by associated questions. This arrangement is designed to allow the interviewer to assist parents both to gain confidence in answering the key questions and to clarify their answers to those questions. Responses to

each key question (either direct or indirect via associated questions) determine the score for its corresponding numbered DAISI item. Examples and criteria for positive and/or negative replies are shown in regular italicized print in the section below.

Questions are arranged below in the order most compatible with the flow of a natural conversation. In this way, responses to more than one domain may be recorded from one segment of conversation. For example, greeting and reaching up to be lifted up from a cot are juxtaposed although these are later analyzed separately as aspects of sociability and gestural communication.

Eye Contact (Item 1)

Did he/she look at you more or less readily as a baby (<2 years) than he/she does nowadays?

Did his/her readiness to give eye contact change at any stage (<2 years)?

Key Question for Item 1: Did he/she have difficulties in the frequency and/or intensity of eye contact? (*This item and item 2 below are subject to a special scoring procedure: They are scored as negative when direct observation of the child reveals poor eye contact at the time of diagnosis and where parents report both that their child's readiness to give eye contact has not changed since infancy, and that they do not see eye contact as a problem for their child.*)

Soothability from Crying (Items 4 and 5)

How would you stop him/her crying as a baby?

Key Question for Item 4: Could you stop him/her crying by picking him/her up? (*Positive responses include those where this strategy worked for at least a few months of infancy.*)

Key Question for Item 5: Could you stop him/her crying by just talking to him/her? (*Positive replies include communicative use of "baby talk," i.e., employing singing, vocalizations, and facial expressions but no physical contact or movement. Negative responses include those for infants described as never interested in social interaction.*)

Greeting, Requesting to Be Picked Up, and Waving (Items 3, 15, and 14, respectively)

What would he/she do when you went to his/her cot after he/she had woken (naturally) from a sleep? Where would he/she be looking?

What would her/his face be like?

Key Question for Item 3: Would he/she greet you? (*Positive responses include manifest pleasure or excitement and/or appropriate facial expression while looking toward parents. Negative responses include a failure to look pleased on most occasions where there was potential for greeting.*)

What would he/she do if he/she wanted to come out of the cot or be lifted from the floor?

Would he/she touch you or the cot while reaching up as if to climb up/out physically?

Did you need to offer your own arms for him/her to lift his/her?

Key Question for Item 15: Would he/she spontaneously lift her arms to be picked up? (*Positive responses cover spontaneous non-tactile gesturing including the support of vocalization, eye contact, etc.*)

Would he/she appear to notice if someone he/she knew well was leaving?

What would he/she do?

Would he/she wave if they (or you) waved?

Would he/she need you to tell him/her to wave or to lift his/her hand for her?

Would he/she wave spontaneously?

How did he/she do it? (i.e., to distinguish from arm flapping)

Where would he/she be looking?

Key Question for Item 14: Would he/she spontaneously and appropriately wave goodbye? (*Positive responses cover spontaneous waving with apparently appropriate communicative intent, as indicated by context, looking toward the other's face, etc. Negative responses include only brief acquisition of waving and/or waving an arm for social or motoric stimulation without apparent understanding of its gestural significance.*)

Lap Games (Items 7 and 8)

What did he/she tend to do during lap games?

Key Question for Item 7: Did he/she enjoy lap games?, e.g., “Round and round the garden,” “Peek a boo.” (*Negative responses included a lack of interest in lap games.*)

Would he/she watch you doing the actions?

Would he/she try to join in?

How did he/she show his/her enjoyment?

Key Question for Item 8: Did he/she actively participate? (*Positive replies require use of body actions, e.g., imitative clapping.*)

Social Engagement During Play With and Without Toys (Items 9 and 6, respectively)

Would he/she be happy for you to play with him/her?

How would he/she react if he/she was already occupied with toys?

Key Question for Item 9: Would he/she be happy for you to join in his/her play with toys or would he/she regard that as an intrusion and prefer to play alone? (*Positive responses include descriptions of infants apparently happy for parents to play alongside them without parents feeling excluded.*)

Would you need toys in order to play with him/her?

Key Question for Item 6: Could you amuse him/her without toys (if say, you were together on a bus or in a doctor’s waiting room where no toys were available)? (*Positive replies may include chatting and/or singing, play with body parts, etc.*)

Showing, Offering and Giving, Referential Eye Contact, Pointing, and Following Points (Items 11, 10, 2, 12, and 13, respectively)

Did he/she sometimes want to draw your attention to his/her toys?

(Or did he/she seem too interested in them to share them with anyone else?)

Key Question for Item 11: Would he/she show you things? (*Positive replies include either holding an object up to another’s field of view or pointing to it and simultaneously looking at the other person. Such referential eye contact also scores positively on item 2, below. Communicative pointing also scores positively on item 12, below.*) (Depending on responses to previous questions. . .)

What would he/she do if he/she wanted you to share his/her experience of a toy?

Would he/she hold it up for you to see? Where would he/she be looking?

Key question for Item 10: Would he/she offer and give objects? (*Positive replies include pausing and looking to the recipient’s face before giving.*)

Would he/she give a toy (or other item) to you?

Was this in response to a request or would it be spontaneous?

Have you known babies who like to give something (e.g., a biscuit) to other people . . . babies who give it very carefully, often breathing heavily as they do so, and then they want it back as soon as they have given it?

Did he/she like to play giving and taking games like that or did he/she tend to “post” or place objects on you instead?

Where would he/she be looking before and during the act of giving?

Key Question for Item 2: Would he/she look both to where he/she was pointing and to you? (Referential eye contact)

What would he/she do if he/she wanted something (e.g., a biscuit) out of reach?

(If reaching) How would he/she position his/her fingers?

Where would he/she be looking?

Key Question for Item 12: Would he/she use pointing communicatively? (*Positive replies include eye- or finger-pointing to request and show items of interest accompanied by eye contact. Negative responses include extension of index finger with no apparent communicative intent.*)

What would he/she do if she saw something of interest like a plane, or an animal across the street?

(If reaching) How would he/she position his/her fingers?

Where would he/she be looking?

Did he/she take notice if you pointed at something or did he/she tend to be preoccupied with his/her own interests?

What would he/she do if you pointed (at near and far objects, e.g., an animal across the street, the correct hole for a puzzle piece, etc.)?

Key Question for Item 13: Could she follow your pointing gestures?

Where would he/she look . . . toward your finger or to where you were pointing?

Expressing Directed Anger and Distress (Item 18)

Did he/she have tantrums?

Where would he/she be looking during these?

What would he/she do if he/she was hurt?

Would he/she let you know how he/she was hurt?

Where would he/she be looking?

Key Question for Item 18: Would he/she appear to direct anger and/or distress with apparent communicative intent? *(Negative responses include toddlers who would avoid looking toward other faces during expressions of anger and/or distress. Positive responses include toddlers who directed anger toward parents when feeling physical pain unrelated to parental behavior.)*

Teasing (Item 16)

Did he/she understand “No” even if he/she chose to ignore it?

Have you noticed some toddlers will still do what they have been told not to do (e.g., touch an electric switch) and will be smiling and looking to their parents at the same time as if they are doing it again *because* they have been told not to do it?

Was he/she a toddler who was interested in doing that?

Can you give examples? Where would he/she be looking?

What would his/her face be like as he/she did it?

Key Question for Item 16: Would he/she tease you? *(Negative responses include enjoyment of playful reprimands, such as being chased, rather than manifesting playful provocation/teasing per se.)*

Can you think of other ways in which he/she would tease you?

Preverbal Turn-Taking and Use of Vocalizations (Items 19 and 17, respectively)

Did he/she make baby noises?

(Positive responses enable progression to the following questions.)

Did he/she make these just for him/herself or did he/she seem to be making them for you to listen to him/her?

How did he/she show that they were for you?

Where would he/she be looking?

Key Question for Item 19: Were his/her baby noises communicative? *(Negative responses include an absence of babbling or parental inability to recall communicative use of babbling despite parental expectation that this occurs.)*

Have you noticed how some babies like you to join in with their babbled noises, so that there is a turn-taking pattern between you and them – as if the two of you are speaking another language? *(Positive answers are required before proceeding.)*

Was he/she the kind of baby who did that?

Were you able to have babbling conversations with him/her?

Did he/she use his/her early words for him/herself or for giving messages to you?

Where would he/she be looking when using them?

Key Question for Item 17: Did he/she take turns before he/she could talk, e.g., with babbled noises? *(Positive responses include turn-taking flows established by (a) infants repeating a babbled noise as if with communicative intent apparently in response to an adult’s imitations of those noises and (b) active silent participation in a flow of interaction using appropriate facial expressions and communicative body actions during a period of mutism.)*

Definition

Autism spectrum disorder (ASD) represents a group of lifelong, complex neurodevelopmental disorders emerging during early childhood and interfering with a person's ability to socially relate to and interact with others. According to the American Psychiatric Association Diagnostic and Statistical Manual, Fifth Revision (DSM-5), the current diagnostic criteria for ASD include deficits in: (a) social interaction and nonverbal communication; and (b) restricted, repetitive movements, behaviors, and interests (American Psychiatric Association 2013). The World Health Organization (WHO) International Classification of Diseases, Tenth Edition (ICD-10) characterizes ASD by impairments in three core areas: social interaction; communication; and restricted, repetitive behaviors (World Health Organization

1994). The ICD-11 is scheduled for release in 2018 and expected to follow the new ASD nosology.

Historical Background

According to the United States Centers for Disease Control and Prevention, ASD now affects 1 in every 68 children (1 in 42 boys and 1 in 189 girls) in the US (Christensen et al. 2016). In 2010, there were approximately 52 million people living with ASD worldwide (Elsabbagh et al. 2012; Baxter et al. 2015). The data on prevalence of ASD in low- and middle-income countries (LMICs) is limited. Most research into the epidemiology, causes, clinical presentations, diagnosis, and treatment of ASD is based on studies conducted in high-income countries (HICs). This has led to a misperception that ASD is more prevalent in HICs versus LMICs. For example, while only 20% of the world's current population resides in HICs, 86.5% of all reported cases of ASD have been in HICs (Elsabbagh et al. 2012; Population Reference Bureau 2015). However, it is important to note that current data in HICs shows that ASD occurs across all levels of socioeconomic status (SES), and the reported association of ASD and higher SES has been due to selected study sampling. Furthermore, uneven rates of diagnosis point to variation in ASD surveillance rates by race and ethnicity, underscoring that children in resource poor regions in HICs may not be appropriately identified (Center for Disease Control and Prevention 2016; Christensen et al. 2016). Barring geographic environmental and genetic variation, there is no reason to expect that prevalence of ASD in LMICs will be lower than that consistently reported in HICs.

In 2007, the United Nations (UN) representative from Qatar had successfully proposed a UN General Assembly resolution creating World Autism Awareness Day. This day, recognized on 2 April every year, encourages all member states to take measures to raise awareness about ASD throughout the world. Further, on World Autism Awareness Day in 2016, the UN General Assembly convened an expert panel that emphasized that

children and adults with ASD and other neurodevelopmental disorders (NDDs) have a special place at the heart of the UN Sustainable Development Agenda and implementation of the Sustainable Development Goals. In 2016, the World Innovation Summit in Health hosted the Autism Forum entitled "A Global Framework for Action" (Munir et al. 2016). There is a growing momentum recognizing ASD globally, and advocating for the needs and rights of children in LMICs with ASD, and their families. There is a need to strengthen national capacities in LMICs within a larger context of global advocacy. This chapter will outline the current knowledge of ASD in LMICs, and highlight challenges currently faced by families, communities, and countries as they aim to advocate for the rights of children with ASD. This chapter will also offer policy recommendations to overcome these challenges.

Current Knowledge

Detection and Diagnosis of ASD

While the timely detection of ASD is a challenge globally, it is a particular problem in LMICs where there is less general surveillance for developmental delays in health and education settings. There are also less opportunities for targeted ASD screening, developmental evaluations, and eventual diagnoses made among high-risk children.

In many LMICs, there is little general knowledge about NDDs, and many parents are not aware of the appropriate timing for developmental milestone skills related to speech and language (Ertem et al. 2007). Review of previous studies in sub-Saharan Africa (SSA) shows that among health workers, a small percentage views ASD as treatable while few others see it as being preventable (Bakare et al. 2016). Community perception of ASD in SSA has a wide range of implications ranging from limited understanding of the disorder, fear of stigmatization, and social exclusion, in the absence of appropriate policies to improve care and community inclusion. As a result, even when parents do have developmental or behavioral concerns, they often still do not reach out to

health care providers because they mostly associate the clinicians with treating acute illnesses. In addition, in many LMICs, the stigma around ASD, as with other NDDs, may be so pervasive as to discourage parents from seeking medical attention when a concern arises, or denying further evaluation or treatment when suggested to them from a medical or educational professional.

In fact, most clinicians in LMICs are not trained in developmental milestones or how to assess them during routine pediatric clinical care (Durkin et al. 2015; Bakare et al. 2016). As a result, developmental delays often go unnoticed also by clinicians, thus children are not referred for further evaluation that could lead to a proper diagnosis. There is also a severe shortage of clinicians who would facilitate more targeted screening, evaluation, and diagnostic procedures for children with ASD and other NDDs in LMICs. Those that do have proper training are mostly congregated in urban settings, leaving large numbers of children in rural regions without diagnostic resources. In the school systems, teachers also lack training and knowledge about ASD, and therefore typically do not pick up on early signs of ASD among children in their classrooms.

Evidence-Based Therapies

Young children with ASD require interventions that target language skills, joint attention, and emotional reciprocity, and therefore treatments should begin as early as possible. Research in HICs has found that early interventions initiated before 3 years of age are likely to have the greatest positive impact on outcomes (Zwaigenbaum et al. 2015). There are evidence-based early interventions, including Applied Behavioral Analysis (ABA); other treatments include speech and language, occupational and physical therapies, social skills groups, as well as management of comorbid conditions such as associated medical (e.g., sleep and gastrointestinal) and neurological (e.g., seizure) disorders, anxiety, and challenging and maladaptive behaviors. In contrast to HICs, the majority of children in LMICs have no access to treatment. In South East Asia with the largest number of children, between 2 and 9 years, the

key barriers to treatment continue to include both the paucity of interventions, as well as lack of trained staff to deliver them outside the reach of specialist centers (Patel et al. 2013). It is feasible to adapt early interventions evidenced in HICs by using “task-shifting” strategies, as demonstrated by the Parent-mediated intervention for ASD in South Asia (PASS) randomized control trial (Rahman et al. 2016). The development of such opportunities is likely to contribute to more optimal care and outcomes in LMICs. The quality of services that are provided is often very variable as well. Children in rural areas, in particular, often have limited access to therapeutic services, which may only be provided in urban settings. Furthermore, many families in LMICs do not have health care coverage to pay for the high cost of services related to ASD and there has been limited adaptation of services that can be provided at lower cost to children and families with few exceptions (Rahman et al. 2016).

Family Support Systems

Families are the constant and consistent source of support for children and as such can wield tremendous influence on the growing and developing child. In all corners of the world, especially where resources are scarce, the family is undoubtedly the vehicle by which education and thus “intervention” and direction for the child can be provided most efficiently and possibly most effectively.

Families whose children are perceived as different feel isolated, alone, and often stigmatized, and too often take on self-blame (Dunst et al. 1994). This is especially true for parents of children with ASD. The pervasive lack of knowledge about ASD magnifies self-doubt, isolation, and stigma that plague many families. Families struggle to know how best to deal with their child’s disability in the home setting or in the community (Hecht et al. 2011) and may not know anyone to ask or to mentor them. The lack of knowledge about ASD coupled with the lack of available role models also prevents the family from learning how their child is best taught and responded to in their homes and communities. This leads to isolation and feelings of stigma.

Many parents of children with disabilities have lower rates of, and diminished opportunities for, employment and advancement than parents of children without disabilities (Emerson 2007). They thus often lack adequate financial resources to pursue formal instruction on how to teach or effectively intervene with their child's special needs; and formal systems' supports are underfunded and scarce (Seltzer et al. 2001; Parish et al. 2009). It is thus incumbent and timely that policy makers assist and support the training of families to best address the needs of the child with ASD and related neurodevelopmental disabilities. This may be especially true in rural and LMIC contexts.

Education

Education has been globally recognized as a basic human right (UN 2008). This perspective has been reflected in a number of international policies including the United Nations Convention on the Rights of the Child, the International Covenant on Economic, Social and Cultural Rights, and the United Nations Convention on the Rights of Persons with Disabilities (UN CRPD; UNESCO 2015). In particular, the UN CRPD, an international treaty passed in 2008, represents an important shift in awareness and advocacy, with an emphasis on considering persons with disabilities as empowered individuals with important rights. These include the right to an "inclusive, quality and free primary and secondary education on an equal basis with others in the communities in which they live." (UN CRPD article 24: UN 2008).

Despite this policy and its current adoption by 162 member states (as of March 22, 2016), children with disabilities continue to face barriers accessing an inclusive public education in many LMICs. In fact, approximately one-third of the over 60 million children still excluded altogether from public schools worldwide are children with disabilities (UNESCO 2013).

The goal of providing children with an inclusive education in mainstream public (government funded) schools is an important one. The path from exclusion to inclusion is a continuum, and many communities fall somewhere in between

with their current practices, which may also vary depending on the severity of a child's disability. While many LMIC countries promote segregated special schools as a means to educate children with ASD and other disabilities, evidence has shown that this can increase prejudice and stigma in societies, and further perpetuate discrimination later in life (Frederickson and Cline 2002). Because segregated schools are often only present in urban areas of LMICs, relying on these separate schools to educate children with disabilities may result in children from rural regions excluded from the education system altogether.

Integration has been a stepping-stone for many countries as they move towards the goal of inclusion. Inclusion with proper support services and accommodation for children with disabilities has been presented as the model learning environment, with evidence showing that it can help all students, both with and without disabilities, reach their full potential (Mariga et al. 2014). Children with moderate to severe disabilities, such as children with both ASD and an intellectual disability, are at highest risk of being excluded from the mainstream educational system in their country. Those with mild disabilities, such as children with ASD without an intellectual disability, may receive their education in the mainstream public education system, but often missing the needed modifications and support services, such as speech therapy and occupational therapy. The lack of enforcement of existing policies that guarantee children with ASD and other disabilities the right to an equal, inclusive education is often due to a shortage of properly trained teachers and appropriate school curriculum. Many LMICs do not provide special education training for teachers, or provide general education teachers with training on how to accommodate a child with a disability in their classroom. Furthermore, appropriate school curriculum and other educational modifications are not present in most school systems in LMICs. Nor do they have resources to develop their own learning programs and materials for children with ASD, and do not have a system for accommodating children with ASD and other disabilities into a regular classroom.

Research and Surveillance

Health research is an important tool for improving the lives of children in LMICs. However, despite the fact that the greatest number of children with ASD live in LMICs, very little relevant research has been conducted in these settings (Durkin et al. 2015). Studies on important topics related to the ASD have mainly been conducted in HIC and therefore provide an incomplete and biased view of the global ASD burden and challenges facing the autism community worldwide. In particular, there is a critical gap in quality epidemiologic research that would accurately describe the prevalence of ASD and other neurodevelopmental disabilities in LMICs.

Proper epidemiologic studies involve the use of validated research tools for systematic clinical screening and diagnosis. Cost of illness studies are also needed to help governments understand the true economic burden of ASD in their country. These types of studies are important for planning and advocacy purposes, resource allocation, and to create a strong justification for the development of provider and researcher training programs, service provision, and additional research. Additional studies are also needed to evaluate the effectiveness of interventions delivered to children with ASD and other neurodevelopmental disabilities in LMICs and the resources required to provide these services. Ideally, results from such studies would enable LMICs to more efficiently utilize their limited mental health resources by taking a systematic approach to prioritize the utilization of the most cost-effective interventions for treating children with ASD and other neurodevelopmental disorders.

However, researchers in LMICs face a number of barriers in their attempt to conduct quality research related to ASD and mental health care more generally (Sharan et al. 2007). For instance, many LMICs do not prioritize the research questions that would maximize health gains and other priorities within their country. As a result, there is a risk that external research funders will pursue a research agenda that meets their own goals, or the goals of the larger international community, which may not be consistent with the needs of the country. In addition, research is often not

prioritized because it rarely informs policy development in the local context. And too few health researchers in LMICs are trained in rigorous standardized methods, including the responsible conduct of research. Researchers without proper training may produce studies that are of poor quality and have biased research results. Data emerging from HICs underscores importance of controlling for biases in detection when conducting epidemiological studies of ASD.

Future Directions

Diagnosis

To increase rates of early diagnosis, there is a need to first increase the surveillance of developmental outcomes in the home, community, health care, and education settings. Education and awareness campaigns have been successful in educating parents in LMICs about ASD. Within the health care system, there is a critical need to provide training and education to clinicians at the primary care level while also developing additional specialized training programs for clinicians to perform more targeted screenings and evaluations for ASD and other neurodevelopmental disorders.

At the primary care level, rates of diagnoses can be increased by providing information to pediatricians about the appropriate developmental milestones as well as signs of ASD and other neurodevelopmental disorders. This information should also be incorporated in the medical curriculum of clinicians. Guidelines should be developed that include strategies to include general developmental surveillance into routine pediatric visits. Structured developmental pediatrics, psychology, and child psychiatry training programs are also needed to train more clinical personnel to perform screenings and evaluation procedures targeted at individuals deemed to be at high risk of ASD and other developmental disabilities based on surveillance in the home, clinic, school, and community settings. The training of these specialists must occur in parallel with greater accessibility to simpler surveillance, screening, and diagnostic tools that can be used with fewer resources than those currently used in HIC.

Teachers and educators are valuable resources who spend their days working with, playing with, and watching children. They are already familiar with some developmental milestones. They are also a trusted source for parents. The teachers in the LMICs can be trained in identifying developmental delays, both as part of their school curriculum and further educated on these needs while working in the classroom. Teachers learn about various milestones to watch for at different ages. These activities need to be appropriately adapted to the sociocultural context.

Evidence-Based Therapy

LMICs need formal training programs for health professionals to develop expertise in evidence-based services. High intensity interventions commonly available in HICs should be adapted to be less resource intensive. Even so, the number of formally trained professionals in LMICs will increase slowly.

While this formal capacity is built up, there is an opportunity to reach out to parents of children diagnosed with ASD and train them to provide services directly to their children in their homes. Some evidence has shown that training parents to provide interventions to their child with ASD can result in favorable outcomes including increased language comprehension and reduction in severity of core symptoms of ASD (Oono et al. 2013, Cochrane Review).

For services provided by health professionals, quality control mechanisms such as certifications for training and licensing for programs are necessary to ensure adequate quality. Importantly, providing health care coverage to children with ASD and other neurodevelopmental disorders would help alleviate the cost burden faced by many families who struggle to pay for 11 intervention services of for their child. Expanding existing programs that provide health care coverage for some infectious diseases may be a starting point for providing coverage for larger range of services for chronic and mental illness, including ASD.

Family

To maximize impact and broadly affect families' quality of life, policy makers, governmental, and

nongovernmental organizations (NGO's), need to create and offer services and support to families raising children who have ASD. This is paramount in order for these families and their loved ones with ASD to attain their optimal health and reach their maximum human potential. This also aligns with Article 25 of the United Nations Convention on the Rights of Persons with Disabilities (United Nations 2008).

Community and governmental efforts that have proven to be most effective in assisting families includes the family voice. That is, by allowing families to become part of the national policy discussion, family concerns are more directly addressed (Hecht et al. 2011). Access to the perspectives of families allows professionals and systems to learn from first-hand experiences. This can result in adjustments to services that meet their needs resulting in improved support to families.

A three pronged approach would include: (1) connecting families to each other; (2) creating programs; and (3) providing sustained support. This is important to up-to-date information, and to policy makers are the three most important elements that families have identified as critical in the effort to support them and their affected child (Hecht et al. 2011).

- (1) *Connecting families to each other:* These connections go a long way towards assisting families in recognizing that they are not alone; that there have been others who have experienced what they are facing and have been successful. Supplying families with needed information is crucial in assisting them in understanding and supporting their family member to reach their potential. These efforts have often been organized and directed by families seeking other families who have experiences similar to their own. Family-led organizations and coalitions have shown to be an effective and low cost way to assist in these connections (will add citation). Policy and program directors can enhance these efforts through providing relatively minimal support to initiate and sustain structures (e.g., developing support groups, family events/

activities) that allow families to connect to other families. In situations where the internet is available, many connections can be initiated online where families can meet and even communicate directly with other families about their concerns (New England Genetics Collaborative 2016). These connections are enhanced when families receive up-to-date information about their child's condition and how best to work with their child (ASC 1016). This is an effective communication strategy that can work especially well in rural and less developed countries when the technology can be utilized. A successful initial effort has been to discover how families currently connect with one another. Leaders in the family movement must be identified and supported so that they can effectively articulate what families need. By inviting families into professional and governmental programs, the needs of families rise to the top and family perspective becomes evident and concerns are heard and addressed (see the ► [Family Therapy](#) case study). Connecting families and family leaders to governmental initiatives is the third part of making connections. This is critical in the development of programs and is a major part of the social strategy that begins to change what families can be offered and how families are supported. These efforts impact the policies that are then developed and that create programs. Policy makers begin to hear the family voice and understand the needs and what would help the most. Integration of the family perspective results in the development of the most effective strategies and policies to address the problems.

- (2) *Creating programs:* Opportunities to participate in programs need to be developed that educate families about the conditions that impact their children. These educational programs can be made readily available by utilizing online training. Policy makers should create the infrastructure that grants the family access to professionals and community health workers. Training opportunities may vary such that information provided to families can range in complexity. Training in skill

development for the families in interacting with the affected family member, and support for parental coping skills may also be provided. This type of system support mechanism can assist in the child's development and help to reduce parental stress. By inviting families to be part of the decision-making process, the programs are more likely to be successful.

- (3) *Providing sustained support:* Although early diagnosis and treatment have been shown to increase the adaptability and skill levels of children with ASD, support for the growing child and family must be sustained over time. The developmental trajectory of the child brings about new challenges and additional or changing needs for support. Much information focuses on the young child and the early interventions provided shortly after diagnosis, but support during development must also be addressed (Hecht et al. 2011). Programs need to be developed that assist the growing child in reaching their full potential throughout their development with an emphasis on supporting an individual's independence and full inclusion into their communities. As families strive to better understand and provide for their children with ASD and related neurodevelopmental disabilities, community health care workers and other professionals (including teachers or school personnel) can be an effective and efficient way to provide the first level of response for families. These teachers or community workers need to be trained to help families understand and cope with the issues they are facing. The Richmond-Kotelchuck Model for Policy Development can serve as a dynamic representation of what is needed for successful policy implementation and outcomes. We have the basic knowledge regarding expanding needs of families whose children have ASD, and there are social strategies that can be utilized that support families. It is up to the political will of policy makers to allow these supports to flourish by welcoming the family perspective into governmental

initiatives in this area (Richmond and Kotelchuck 1983).

Education

There is a critical need to provide a broader set of training programs and certifications to teachers in LMICs that would facilitate the inclusion of children with disabilities into mainstream public schools. Ideally, these programs should be structured to provide special education training to a group of educators as well as provide general education teachers with skills that would allow them to knowledgeably accommodate children with disabilities such as ASD into mainstream, inclusive classes.

There is also an opportunity to train special education teachers in skills and interventions that would improve their work with children with ASD specifically, including applied behavior analysis practices, and peer-mediated intervention (National Autism Center 2009). In parallel to these training programs, there is a need to provide special education teaching and learning resources that can be adapted by individual school systems. For children with ASD and moderate to severe intellectual disabilities, there may be a need to create a separate core curriculum based on the general needs of this group. Goals for these children may include educational, therapeutic, and social ones, including: reading literacy and comprehension, math, social science, sensory therapy, communication and social skills, and functional and life skills. Children with ASD without intellectual disabilities may follow a general education with added support and modifications based on their specific therapeutic and learning needs (Fogarty and Lofland 2015). Efforts should also be made to tailor special education goals to the specific needs of each child. A common strategy for doing this in higher resource settings is to create individual education plans (IEPs) for each child that takes into account their specific needs and goals. These plans can include special arrangements for learning tasks and exams, allowing for exemptions for assignments and assessments, extra time for learning tasks and tests, and

adaptation of the conditions or the format of the task (UNESCO 2015).

And finally, systematically collected data is a central element to monitor educational goals for children with ASD and other disabilities. As part of this, governments need to provide a system and infrastructure that enables school systems to collect and report data on the progress of children in the school environment. This is typically done through annual assessments of student progress. To prioritize and act on these goals, countries should develop an action plan with clear targets and a timetable for implementation. This action plan should be overseen by a core group of administrators within the Ministry of Education that are held accountable for reaching targets by pre-specified deadlines. These goals also create a parallel need for community awareness and education with regards to the benefits of including children with ASD and other disabilities into mainstream schools. These advocacy efforts are often best accomplished by building partnerships between schools, parents, and other stakeholders. It should also be noted that when full inclusion does not seem feasible for a given country, integration of children with ASD and other disabilities into the mainstream school through the coexistence of general education and special education programs within the same school could be an important step to full inclusion.

Research and Surveillance

As an international priority, the World Health Organization (WHO) has urged countries to improve research surveillance frameworks and information systems to better capture data on ASDs (WHO 2013). On a national level, research questions should be prioritized to accommodate both needs and preferences of stakeholders in the local context, and should not be set solely by external research funders. Researchers and policy makers in LMICs should drive a research agenda based on local factors including data that would help with advocacy efforts and creating priorities for national action plan.

There have been different methods used to develop consensus on national research priorities,

and the optimal approach will vary by context. However, nine common themes for best practices in priority setting have emerged in the literature and were summarized by researchers at the WHO in 2010 (Viergever et al. 2010). These best practices are summarized in the appendix. Following the setting of ASD research priorities, it is important to have trained researchers to implement the action plan. However, there are often not enough highly trained researchers in LMICs due to a lack of research-training opportunities. To increase the number of training opportunities, LMIC governments should partner with HIC governments and universities to prepare ASD researchers in high quality research methods. As these training partnerships develop, it is also important to internally strengthen mental health training opportunities in schools of public health and medicine (Sharan et al. 2007), including training in public health research methods, knowledge diffusion, leadership, mentorship, and advocacy (Thorncroft et al. 2012).

While funding for such capacity building is often a barrier, external donors should be encouraged to systematically include capacity-building programs and funding that is earmarked towards capacity-building goals in their projects. As this capacity is being developed, the ASD research environment also needs to be strengthened within LMICs. Critical components of an enabling research environment include appropriate research policies, including procedures to monitor and review ethical considerations in human subject research, basic infrastructure setup that includes administrative support within research centers to oversee research contracts and finance, equipment and supplies, and access to resources such as published literature (Sharan et al. 2007). To help with this last goal, in 2002, the WHO developed the Health InterNetwork Access to Research Initiative (HINARI) in collaboration with major publishers to enable researchers from LMICs to gain access to health research literature. Today approximately 15,000 journals (in 30 different languages) are available to health institutions in more than 100 LMICs (“HINARI Access to Research in Health Programme,” 2016). While the development of a

stable research environment certainly requires upfront investment, over time it will save time and resources by allowing for easier administrative access to research funds and stronger partnerships with funded research programs. Integrating with the health research systems that are already in place, such as those for infectious diseases, can enhance synergies and create a more sustainable national research platform going forward. Strong research partnerships between academic groups, NGO, and governmental entities also create more stable environments and important synergies moving forward.

Developmental Apraxia

Susan Latham

Department of Communication Disorders, St. Mary's College (IN), Notre Dame, IN, USA

Synonyms

Childhood apraxia of speech (CAS)

Short Description or Definition

A motor speech disorder characterized by difficulty acquiring speech, inconsistent sound errors, and groping behaviors during speech in the absence of weakness or paralysis. Symptoms are similar to verbal apraxia in adults; however, the underlying motor impairment significantly impacts phonological development (Maassen 2002). Hallmark characteristics consistent with childhood apraxia of speech include vowel errors or distortions, highly inconsistent speech errors, and inappropriate prosody.

Developmental Change

Annette Karmiloff-Smith
Birkbeck College, London, UK

Definition

Developmental change is the process of change that occurs in human beings throughout development.

Gene expression, brain function, cognitive processes, behavior, and environmental factors all involve multiple cross-level interactions, and all are characterized by dynamic developmental change over time. The study of any neurodevelopmental disorder, be it autism spectrum disorders (ASDs) or those of known genetic origin like Down syndrome (DS), Williams syndrome (WS), fragile X syndrome (FXS), or velocardiofacial syndrome (VCFS), must focus on full developmental trajectories from infancy to adulthood, examining how domains interact differently over time.

Developmental Change at the Genetic Level

Many studies map specific genes to specific behaviors, but rare are those which take account of changing gene expression over time. Yet, if a gene is expressed widely initially and becomes increasingly confined to certain brain regions, or if a gene is expressed much more during learning but less during subsequent behavior, then the mapping from gene to behavior will change.

Developmental Change at the Neural Level

The brain is not static; it changes significantly after birth in terms of structure and function. Functionally, one often witnesses the child brain initially processing inputs bilaterally. With development, however, neural networks become

increasingly specialized and localized such that, for example, face processing starts out bilaterally and becomes predominantly right lateralized, over developmental time, in a network including the fusiform gyrus. Likewise, the processing of certain aspects of language, for example, the use of, say, articles, starts out bilaterally but becomes increasingly left lateralized. By contrast, in some neurodevelopmental disorders, this progressive fine-tuning of specialization and localization of function fails to occur, and processing continues to be bilateral, even when the relevant overt behavior is quite proficient.

Developmental Change at the Cognitive Level

In the study of neurodevelopmental disorders, it is critical to differentiate between identical overt behavioral scores and the underlying cognitive processes that sustain them. For example, face processing may be proficient in a disorder, with scores “in the normal range,” but the underlying cognitive processes rely on featural analyses, whereas in the typically developing child, processing has moved from featural to configural processing over developmental time.

Developmental Change at the Environmental Level

The environment is not static either. In all neurodevelopmental disorders, parents respond to the subtle differences in their atypical offspring, and thus, the dynamics of parent-child interaction change over time. For example, when learning language, the parents of typically developing children tend to let their children temporarily make overgeneralizations (e.g., “dog” for all animals), whereas parents of atypically developing children tend to correct immediately in the fear, perhaps, that they otherwise may never learn the correct term. However, overgeneralization often helps the development of categories (e.g., “animal”), and subtle differences in the ways in which the environment responds to the atypical child may give

rise to the learning of individual exemplars rather than categories.

In conclusion, developmental changes must be taken into account at every level of analysis.

Developmental Continuum (Principles of TEACCH)

Joyce Lum and Kristin Hodgson
UNC TEACCH Autism Program-Charlotte,
Charlotte, NC, USA

Synonyms

[Developmental shifts across lifespan](#)

Definition

The developmental continuum is a dynamic process characterized by milestones and challenges

that occur from infancy throughout adulthood. The interaction of typical developmental issues with ASD is complicated. Milestones may be reached earlier or later than typical peers and at an atypical rate or order; across domains, a scattered skill profile may also be noted. The challenges that an individual with ASD faces may mirror those of his or her typical peers (e.g., entering school, coping with bullying, developing self-image, managing life changes) but may be exaggerated or occur at different points in development. In addition, it is now recognized that ASD does not protect one against other possible diagnoses or challenges, such as anxiety, depression, substance abuse, and other co-occurring disorders. Rather, the interaction of ASD with the typical developmental processes may exacerbate or trigger these issues. Therefore, an initial evaluation should be not solely for diagnosis but also for the comprehensive evaluation of cognitive, adaptive, behavioral, emotional, and psychiatric functioning and should be updated over time.

There are currently many evidence-based treatment practices for individuals with ASD. However, the selection of appropriate treatments is complex, leaving families without clear direction in seeking and selecting services. Comprehensive evaluation identifies the current skill level and needs of an individual with ASD and thus facilitates the development of specific goals. In addition, as the individual needs of the person with ASD changes, the appropriate treatment may also change, even throughout adulthood. Updated evaluations reveal the trajectory and pattern of skill development and the efficacy of any treatments being used and allow for selection of new treatments as appropriate. Families' sense of urgency to intervene may vary across the developmental continuum, with life transitions triggering a recognition of increased need.

Like individuals, families are dynamic and follow a general developmental pathway. This is true of families with typical children as well as those with ASD though, as with individual development, the challenges experienced by the latter are likely to be exacerbated and the changes less linear. The particular needs of a family with a child with ASD tend to correspond to the age of

the child. When the child is an infant/toddler/preschooler, families are recognizing developmental differences and managing the impact of these on the family, then dealing with diagnosis of ASD and associated grief. In the middle childhood years, families focus on school concerns, adaptive skills, and issues related to puberty. In adolescence and adulthood, common themes center on collegiate, vocational, and/or residential preparation as well as self-advocacy, guardianship, and interpersonal supports. This pattern of development is not universal, however. Just as professionals must fully assess an individual to ascertain skill level before implementing intervention, they must understand the current family interactions, challenges, needs, and foci so as to have a greater impact on that family. Current recognition of the importance of adaptive behavior provides an opportunity for families to increase positive outcomes through intervention and teaching in the home and community to facilitate increases in independence across the lifespan.

The developmental continuum contributes to a founding principle of the UNC TEACCH Autism Program, which is that of family involvement in service delivery. In working with clients, TEACCH promotes the view that the specific needs of the individual with ASD can be best met by recognizing the family's needs and by working simultaneously with caregivers to address them. TEACCH has always seen parents and caregivers as the experts, advocates, and teachers for their children and the professional's role as one of the facilitators in helping the individual with ASD to maximize their level of independence and in helping family members gain additional tools to be as effective as possible in their roles. There is a current recognition that aging individuals with ASD continue to need support that may differ from that at younger ages, as their health and financial needs increase and their family support circle may decrease. Across the developmental continuum, the needs of individuals, families, and support systems must be the focus of assessment and intervention in order to most effectively serve individuals with ASD.

Developmental Coordination Disorder

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Cerebral palsy](#); [Dyspraxia](#)

Short Description or Definition

Children who present marked difficulties with motor movements have been known since ancient times. Terms like “cerebral palsy” have been used in the past particularly to refer to situations where these problems appear to relate to some specific process, e.g., birth trauma. Although a medical etiology is sometimes seen, this is less likely in cases that are less severe. The term “developmental coordination disorder” is currently used.

Categorization

In DSM-IV, this condition is defined based on the presence of motor difficulties greater than expected (given age or developmental level) and not due to some other conditions like autism. Motor difficulties are sometimes seen with other developmental problems, e.g., language or learning disorders. Interestingly some work has been done on the constellation of social-emotional difficulties, motor, and attentional problems (the DAMP syndrome; see Ehlers et al. 1997).

Epidemiology

The condition may be seen in up to 6% of children of school age. Boys are more frequently diagnosed than girls (although various factors may make it less likely that subtle difficulties in girls lead to lower rates of referral).

Natural History, Prognostic Factors, and Outcomes

Various factors determine outcome. Often the ultimate outcome is best when motor difficulties are mild and isolated (i.e., not associated with other developmental problems). Sometimes motor delays can lead to other problems such as social isolation and, in turn, to anxiety and mood problems.

Clinical Expression and Pathophysiology

Motor skill difficulties can arise because of a host of factors. These range from problems during pregnancy in the mother, birth trauma, and perinatal difficulties (e.g., hypoxia or severe prematurity). Speech-language issues can be noted reflecting, in some cases, oral motor difficulties. Often a combination of some degree of developmental immaturity and a more specific motor vulnerability is involved.

Evaluation and Differential Diagnosis

Neurological and specialized occupational and physical therapy evaluations are indicated if motor difficulties are severe and/or significant. The presence of unusual movements, problems with hyper- or hypotonia, and of specific neurological symptoms can also prompt referral. Various tests of gross and fine motor skills as well as visual motor integration and of dexterity can be administered. These help to document areas of difficulty and establish baselines for intervention. In some cases, use of auxiliary aids/devices may be helpful, e.g., in children with Asperger’s disorder who have problems with cursive handwriting, use of a laptop to teach keyboarding skills can be indicated.

Treatment

Rehabilitative approaches are helpful. Both occupational and physical therapy approaches can be used to address fine and gross motor problems. Within schools, adaptive physical education can also be helpful.

Developmental Delay

Michelle Lestrud

The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Definition

Developmental delay is a significant lag in reaching the typical childhood milestones in the areas of language; cognition; social, emotional, adaptive functioning; and motor development. Each milestone is reached within a certain number of months based on research of typically developing children. When a child does not reach one or more of the milestones during the expected time frame, then he or she may be suspected of having a developmental delay.

In the context of public education, the IDEA definition of developmental delay is only inclusive of children aged three to nine and lists physical development, cognitive development, communication development, social or emotional development, and adaptive development as the areas to assess for a suspected disability. Children with autism often display delays in several of these areas, which may be the first warning signs that lead to further assessment and evaluation. Assessing developmental delays should be a component of diagnosing autism as the key deficits that characterize the disorder are directly linked to skills typically learned during natural developmental cycles. Skills that may be deficient in early development for individuals with autism include areas such as basic purposeful communication, initiating social interactions, and imitating functional use of objects or toys. Developmental delays may result in gaps in skill acquisition and/or performance and create widely varying strengths and weaknesses in some children.

Evaluations used to assess developmental delays vary among practitioners and typically include a measure of adaptive functioning with assessments such as the Vineland Adaptive Behavior Scales. This rating scale can be used to document delays in social and communicative development in individuals with autism. In addition, there are a number of motor assessments available, tests to measure cognitive levels, and specific communication assessments.

Developmental Disabilities

Isabelle Rapin

Neurology and Pediatrics (Neurology), Albert Einstein College of Medicine, Bronx, NY, USA

Synonyms

Academic disability; Specific learning disability

Definition

Learning disability is not used here to refer to overall intellectual handicap (i.e., “mental retardation”).

- Developmental disability refers to unexpected delay or deficiency apparently healthy young children experience in the acquisition of a learned cognitive/intellectual skill (as opposed to a sensory-motor skill) despite

overall intellectual competence, attention and motivation, lack of auditory or visual handicap, and sufficient exposure to appropriate models and educational opportunity in an adequately supportive and nurturing environment.

- Developmental disabilities are extremely prevalent; they are dimensionally defined with fuzzy borders even though they denote atypical development of particular brain circuitries.
- They are both genetically and environmentally influenced.

Major Types

1. *Developmental language disorder (specific language impairment (SLI), dysphasia)* – in affected infants, the disorder presents as variably delayed/impoverished expressive language. There are three main clinical types, each with subtypes:

- a. *Expressive type*: impaired speech production and articulation (phonology) with adequate comprehension. Prognosis generally fairly good, except in the most severe subtype – verbal dyspraxia (not to be confused with oromotor disability, a deficit in motor control of the speech musculature).
- b. *Mixed receptive/expressive type*: comprehension equal to or somewhat better than expression. Phonology, grammar, and vocabulary affected. Prognosis variable, often the harbinger of dyslexia, and poor when phonologic decoding is severely defective.
- c. *Mainly receptive type*: impaired comprehension of discourse. Often overlooked when speech articulation, grammar, and vocabulary are spared. Particularly frequent but not exclusively so in verbal children on the autism spectrum.

Note: *Language disorders in children on the autism spectrum (ASD)* – Pragmatics, i.e., the communicative/conversational use of language, universally, characteristically, and permanently impaired. The prevalence of types of language disorders in ASD children differs from that of

dysphasic children: some have mixed expressive/receptive disorders; very few have expressive disorders with adequate comprehension; most verbal children have receptive disorders with telltale echolalia, use of scripts, incessant questioning, perseveration on self-selected topics, answering questions off topic, and aberrant prosody.

2. *Reading disability (dyslexia)* – difficulty learning the alphabetical code of written language at school age. Dyslexia is often the residual of a developmental language disorder with difficulty making fine auditory discriminations between speech sounds. Most dyslexic individuals eventually learn to read more or less efficiently, but retain difficulty reading pronounceable non-words and, often, poor spelling (*dysorthographia*). Less frequent causes include visual discrimination difficulties or sequencing problems implicating deficient working memory.
3. *Mathematical disability (dyscalculia)* – difficulty with mental or written arithmetic, geometry, word problems, or other mathematical operations. Identification of its cause requires detailed neuropsychologic investigation. Attention deficit disorder contributes to dyscalculia and complex arithmetical operations. Visuospatial problems impair not only geometry but also written arithmetic.
4. *Dysgraphia* – poor handwriting, associated or not with *dysorthographia*. Either due to an overt or subtle motor deficit or difficulty in learning complex motor skills (*dyspraxia*). A large sloppy handwriting (dyspraxia) with excellent spelling (superior rote memory) often characterizes ASD.
5. *Others* – tone deafness, grossly deficient ability to draw or classify can be considered learning disabilities when they interfere with children’s acquisition of required skills.

Developmental Intervention Model

Kyle Sterrett¹ and Amanda C. Gulsrud²

¹University of California, Los Angeles, Los Angeles, CA, USA

²UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, USA

Definition

The developmental approach to intervention draws upon the knowledge of typical development to design treatment objectives for children with autism spectrum disorder (ASD). Child development research informs the developmental processes that determine goals, measure change, and guide treatment practices. The main pillars of this approach include the selection of developmentally appropriate targets, individualized instruction by focusing on child preferences and interests, and the incorporation of family needs, values, and preferences into intervention objectives. A number of developmental models exist in the early intervention literature of children with ASD including the Floortime and Developmental Individual-difference Relationship models (DIR; Greenspan and Weider 1999), Relationship Development Intervention (RDI; Gutstein and Sheely 2002), Hanen Centre programs (Coulter and Gallagher 2001; Sussman 1999), Preschool Autism Communication Trial (PACT; Green et al. 2010), and Social Communication, Emotional Regulation and Transactional Support (SCERTS; Prizant et al. 2006) models, to name a few. Contemporary behavioral approaches to early intervention for children with ASD, often referred to as Naturalistic Developmental Behavioral Interventions (NDBI; Schreibman et al. 2015), also emphasize developmental objectives and to

varying degrees utilize developmental principles (e.g., Joint Attention Symbolic Play Engagement and Regulation (JASPER), Kasari et al. 2006; Pivotal Response Treatment (PRT), Koegel and Koegel 2006; Incidental teaching, McGee et al. 1999; Reciprocal Imitation Training (RIT; Ingersoll 2010); the Denver Model, Rogers et al. 2000; and Early Start Denver Model (ESDM), Rogers and Dawson 2010).

Historical Background

This treatment approach has its origins in our understanding of how children learn through typical daily social interactions. Teaching during naturalistic, play-based, and developmentally appropriate activities has a long history in the typical early childhood literature to ensure motivation, cooperation, and engagement (Fein and Rivkin 1986; Copple and Bredekamp 2009).

In recent years, these principles have also been applied to children with developmental disorders, such as ASD. Most commonly these interventions focus on the core domain of social communication and include specific emphasis on joint attention, social engagement, and early expressive language (e.g., PACT, SCERTS, RDI, JASPER, Hanen). Several comprehensive treatment approaches have also adopted a developmental framework (e.g., Denver model, ESDM, PRT).

Rationale or Underlying Theory

The underlining theory behind developmental treatment approaches is that each child is an individual with corresponding strengths and weaknesses. Not every child has the same profile of development, especially children with a heterogeneous disorder such as ASD. The developmental approach to intervention strives to tailor curriculum to the needs of each child and provide opportunities for learning skills that are appropriate to the child's current level of functioning as well as scaffolding instruction to more developmentally complex skills within the child's milieu. A developmental framework for early social-

communication intervention pulls from the extensive literature on both incidental teaching (McGee et al. 1985) and the importance of linguistic input to language acquisition (Hoff-Ginsberg and Shatz 1982). This teaching approach is child-centered and child-directed and involves such strategies as following the child's motivations and interests, offering choices within activities, responding to child initiations, and expanding on a child's verbal and nonverbal communicative bids (Prizant et al. 2006; Wilcox and Shannon 1998). Unlike traditional behavioral approaches that are adult-facilitated and stick to a strict hierarchy of program objectives, developmental models strive to follow the child's interests in a naturalistic learning environment. The hope is that by embedding learning opportunities within highly motivating and natural contexts, children will be more apt to participate and the total amount of intervention or dosage each day will increase. An underlining goal of developmental approaches is to foster a deeper connection between the child and a social partner (often the parent) that results in meaningful teaching opportunities.

Goals and Objectives

Several common goals exist across early developmental interventions for ASD. These goals include the emphasis on individualized treatment and targeting developmentally appropriate skills. A majority of developmental interventions emphasize social-communication outcomes for children with ASD, with a special importance placed on children becoming effective communicators. Some programs, such as the Walden preschool, also place an emphasis on early interactions with peers. Additionally, there is an emphasis on the child's emotion regulation abilities and the provision on developmentally appropriate supports for student learning. The SCERTS model emphasizes the need to help the child regulate arousal as a foundation to early intervention. Other developmental models also

believe that helping the child reach the optimal level of arousal is an early developmental skill necessary for successful learning (e.g., DIR, JASPER, ESDM). Another common theme is to provide learning opportunities within the natural social context of daily activities. This includes embedding intervention objectives within play-based activities and daily routines of living and providing support and training for parents to generalize treatment objectives to the home environment.

Treatment Participants

Developmental approaches are typically applied during the early intervention period for children with ASD. Some interventions have been applied to children as young as 12 months of age (e.g., ESDM and JASPER). Typically, restrictions regarding participation are not made based upon child developmental characteristics, such as cognitive, language, and adaptive functioning. With the increasing emphasis on early detection and intervention, it follows suit that these models would support the development of the youngest children affected by the disorder.

Some attempts have also been made to apply developmental models of intervention to older children and adults. The JASPER intervention is a modular treatment that has been tested for efficacy in a wide range of children from toddlers to older nonverbal and school-aged children. Principles of PRT are used across the lifespan. Overall, participants are typically in the preschool range and so more research needs to be done to assure that children and adults across the lifespan can benefit from developmental treatment approaches.

More recently there has also been an increased focus on serving children from diverse and under-represented backgrounds in some development intervention models such as JASPER and the Parent-Mediated Intervention for Autism Spectrum Disorders in South Asia (PASS), a modified version of PACT (Rahman et al. 2016).

Treatment Procedures

Developmental interventions use naturalistic teaching strategies in a variety of settings. The goal is for treatment to be embedded within everyday social experiences; thus, many of the developmental intervention models are play-based. Teaching objectives are embedded within these highly motivating play activities. Research in typical development has shown that children who are allowed to follow their preferred attentional focus see direct benefits on communicative growth (Akhtar et al. 1991; Tomasello and Farrar 1986). Thus, it is believed that children with ASD will also benefit from having more autonomy in the choice of activities and more opportunities to lead the interaction.

Developmental interventions incorporate the use of a wide range of treatment settings including clinics, schools, and the home. Many of these treatments are adapted for use across multiple settings. For example, the ESDM can be applied in center-based preschools, inclusive preschools, and the home environment. PRT has been applied and has empirical support for its use across these settings. JASPER has been validated in randomized controlled trials across a number of settings including clinics, homes, inclusive and center-based preschools, and community settings.

Instruction is also delivered using a variety of methods. Many developmental models will have a portion of the instruction delivered in a 1:1 teaching model with a trained therapist and the child (e.g., ESDM, PRT, JASPER, PACT, SCERTS) and also group settings (e.g., Denver Model, JASPER). Most recent interventions involving parents utilize to some degree what is known as a parent-mediated model. In this model, the parent and child are interacting together with a trained clinician who serves as an active “coach” for these social interactions so that the parent receives immediate feedback.

Efficacy Information

Several developmental early intervention programs have been tested for efficacy. In recent

years, there has been a rapid increase in the methodological quality of interventions testing developmental approaches and there is promising evidence of improvement using these models. One frequently studied approach is the Denver Model and ESDM by Rogers and colleagues. To date, they have numerous peer-reviewed papers on the efficacy of this intervention. The early work using this model utilized a within-subject pre-/postdesign, which as a method may not be adequate for determining effective treatments. Later work involved some quasi and true experimental designs including one randomized controlled clinical trial (RCT) of ESDM, which suggests evidence of improvement in the domains of cognition (DQ), language, and adaptive functioning (Dawson et al. 2010). A more recent RCT of a parent-mediated ESDM approach found no treatment effect on parent and child outcomes (Rogers et al. 2012).

Another treatment approach that has gained scientific support is PRT. Utilizing single-subject methodology, PRT has been documented to improve social skills, disruptive behaviors, responsivity, language, and other social behaviors (e.g., Koegel and Frea 1993; Koegel et al. 1992a, b). Recent RCTs of PRT have been conducted finding increased frequency of verbal utterances and mean length of utterances (Hardan et al. 2015; Mohammadzaheri et al. 2014). One study compared PRT to the Picture Exchange Communication System (PECS) and showed no treatment differences, but both groups increased over time on parent-report and standardized measures of expressive language (Schreibman and Stahmer 2014).

Studies by Kasari and colleagues have shown effectiveness for JASPER, a developmental social-communication intervention for toddlers and preschoolers with ASD. In several RCT trials, children randomly assigned to interventions targeting core deficits of ASD including joint attention and symbolic play made significant gains in joint attention initiations and symbolic play, respectively (Kasari et al. 2006), and also both made significant gains in expressive

language at a follow-up visit 1 and 5 years later compared to participants in a control condition (Kasari et al. 2008, 2012). Similarly, in several RCT designs of toddlers and preschoolers with ASD and their caregivers using a parent-mediated approach, children improved in their joint attention, play, and joint engagement with their caregivers (Kasari et al. 2010, 2014, 2015). JASPER has also been tested in a number of deployment trials where the intervention was carried out by teachers and community providers, not trained interventionists, but showed comparable effects to the clinic based trials (Chang et al. 2016; Kaale et al. 2012; Shire et al. 2016).

SCERTS has almost 30 years of clinical practice, and recent research into its efficacy has been conducted through the Early Social Interactions Project (Wetherby et al. 2014). Effects were seen on children's social communication, receptive language, and adaptive functioning. Similarly, DIR/Floortime has recent evidence supporting its efficacy. Three RCTs have been conducted in preschool aged children with some effects seen on children's broad social communicative functioning, regulation, and autism symptomology (Casenhiser et al. 2013; Pajareya and Nopmaneejumruslers 2011; Solomon et al. 2014). The first two trials have some methodological issues that limit the interpretability of the findings, but the most recent trial found that children receiving the DIR/Floortime-based treatment saw improved diagnostic classification, but no effects were observed on standardized language or cognitive measures.

The PACT intervention has been tested in two recent RCTs, one which took place in a clinic setting (Green et al. 2010) and another in community settings in south Asia (Rahman et al. 2016). The clinic-based intervention found positive effects on children's initiations and shared attention, while the community study found effects only for initiations.

These studies and others like them illustrate the trend toward efficacious treatment in ASD research.

Currently, researchers are focused on identifying the moderators of interventions and the exploration of which treatments work best for different populations of children with ASD. There is a clear need for more research into this area to establish stricter guidelines for "best practices" in autism intervention. Although there is promising evidence for the efficacy of developmental approaches in early intervention for ASD, these developmental models need to be tested against other approaches of early intervention (e.g., DTT) to better answer the question of which treatments work best for the wide range of children affected with the disorder. A number of these comparative efficacy trials are currently underway.

Mechanisms of Change

In recent years, there has been a heightened focus on what are often referred to as the *active ingredients* of developmental interventions. Active ingredients are those factors within an intervention that are driving the treatment effect on a specific outcome. Attempts have been made to isolate the active ingredients of both PACT and JASPER. In the PACT trial, ADOS-g scores were mediated by parental synchrony and children's initiations (Pickles et al. 2015) and in JASPER one strategy, Mirrored Pacing, mediated the treatment effect on children's joint engagement (Gulsrud et al. 2015). Further efforts to understand the mechanisms of change of efficacious developmental interventions will continue as the evidence base grows.

Outcome Measurement

Many of the early developmental interventions target social communication in our youngest children affected with ASD. It follows suit that outcome measures for these interventions would tap into domains of social and communicative functioning. Broadly, there are two types of outcome measures to consider, those which are proximal

and distal to the intervention procedure. Proximal outcomes are directly targeted by the intervention and distal outcomes are downstream effects that are expected but not explicitly targeted. The JASPER and PACT interventions have proximal outcomes such as joint engagement and shared attention that are directly targeted in the interventions, and it is expected that these changes in proximal outcomes will lead to distal effects on expressive and receptive language. It is important that both proximal and distal outcomes are carefully selected. An intervention can have strong effects on proximal outcomes but show no effect on distal outcomes, or can show change across both. Important to note is that distal effects cannot be seen without first moving proximal outcomes. The importance of follow-up and long-term measurement is therefore a strong point of emphasis in developmental interventions although the cost of measuring data over time and issues of attrition often limit the feasibility of long-term follow-up periods.

The measures used in developmental interventions vary widely. They include standardized measures of language, cognitive ability, and autism symptomology (often distal outcomes) such as the Mullen Scales of Early Learning, the Reynell Developmental Language Scales (Reynell 1977), and the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 2000). Parent reports include measures of language and adaptive functioning such as the MacArthur-Bates Communicative Development Inventory (Fenson et al. 1993) and Vineland Adaptive Behavior Scales (Sparrow et al. 2005). A number of interventions utilize idiosyncratic measures (often proximal outcomes) that code for specific behaviors targeted by the intervention such as engagement, play, and gesture use; these coding measures are usually in the context of unstructured or structured play interactions between adults and children. New standardized observational measures, such as the Brief Observation of Social Communication Change (BOSCC; Grzadzinski et al. 2016), which are more sensitive to subtle changes in

the often complex social communication behaviors of children, are also beginning to emerge.

Qualifications of Treatment Providers

Most developmental interventions require specific training to implement. Trained clinicians carry out the models described above with checks for fidelity to instruction standards occurring at regular intervals for several programs (e.g., PRT, ESDM, JASPER). Hanen requires speech and language therapists to implement the intervention. Many treatments also involve the training of parents to generalize program goals to the home setting. Some models also conduct trainings to extend instruction to teachers and community providers (e.g., PRT, JASPER, PACT).

University, Baton Rouge, LA, USA

Definition

Developmental milestones are a set of behaviors, skills, or abilities that are demonstrated by

specified ages during infancy and early childhood in typical development. Developmental milestones are often presented in lists broken down by ages, beginning around 1–3 months of age and progressing through approximately 5 years of age. The Centers for Disease Control and Prevention (CDC) provides easily accessible information through their website (2010). Several categories of skills are often focused on including vision and hearing, social, cognitive, language, motor, and self-help. Parents, day-care providers, teachers, child psychologists, and pediatricians often note emerging concerns regarding development when infants and children fail to reach developmental milestones on time.

While some variation is to be expected among individuals, developmental milestones are used as guidelines to assist in the identification of developmental delays, including autism spectrum disorders. When an infant or child is not reaching developmental milestones or is significantly delayed in meeting them, further assessment and evaluation should be completed. Early diagnosis and early intervention for autism are important for best outcomes. Skills that may be deficient in early development for individuals with autism spectrum disorders include social behavior, joint attention, visual orientation, orienting to noise, response to name, imitation of movement or sounds, and language acquisition including both receptive and expressive language (Watson et al. 2003).

Description

The Developmental, Dimensional and Diagnostic Interview (3Di; Skuse et al. 2004) is a standardized, computer-based diagnostic interview in which individual scores of children from the age of 3 years old and upward in both clinical and normal populations with suspected autism spectrum disorder (ASD) can be scored in terms of their severity, frequency, and comorbidity. It was specifically designed to be easy and practical in its use, requiring minimal training and automation of reporting. The interview offers a dimensional assessment across the full range of autism spectrum characteristics. Subjects, whom the 3Di was primarily developed to assess, were children of school age with normal-range cognitive abilities. With simple modifications, the 3Di can also be used with younger children (from 2 years of age) as well as those with moderate or severe mental retardation. Algorithms can automatically adapt the scoring system for a particular age-group or to allow for a nonverbal subject. If employed for the assessment of preschool-aged children, or those in late adolescence and beyond, some rephrasing of questions will be required. In the case of older adolescents or adults, the interviewer would ask about a specific time when that individual was of an age when the domain of content applied. With minor modification, the interview can be administered as part of the diagnostic evaluation of adults. The 3Di was developed primarily to assist clinicians to make highly reliable diagnoses. It is recommended to use the 3Di in combination with independent observational assessments, such as the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 2000). Validity was established in comparison with the ADI-R, and the ADI-R diagnostic algorithm can be emulated (Skuse et al. 2004). A recent modification enables the DSM-5 ASD criteria to be employed in diagnostic decision-making.

The answers to the questions on the 3Di are provided by parents and scored by a trained clinician (Skuse et al. 2004). The interview contains 183 questions concerning demography, family

background, developmental history, and motor skills. Another 266 items concern characteristics of ASD (i.e., social communication/language, social interaction, and restricted repetitive behaviors and interests [RRBI]), while a further 291 questions relate to current mental states relevant to other psychiatric diagnoses. Designed to sound as natural as possible, the questions must be asked in the same way as they are written, which should sound like a normal conversation with the informant. The 3Di is unique in its construction, as it is neither a completely structured nor a semi-structured interview but a hybrid between these two approaches. Moreover, the 3Di's use of computerized administration aims to ensure high reliability, good discriminant validity, and interviewee acceptability. To minimize the time spent in the face-to-face assessment, a pre-interview package of questionnaires has been designed that can be provided by parents in advance of their appointment and entered onto the computer from record forms. With this option, background information on family structure and biological functions such as motor skills, sleep, and eating/toileting behavior are completed in advance. Questions about autistic symptoms are always asked face-to-face. The full ASD interview, which is recommended for complex cases, can usually be conducted in 90–120 min, with pre-entry.

The 3Di was computerized to improve reliability. Computerization would ensure good inter-rater and test-retest reliability with minimal training, for it made rater drift less likely. The 3Di has a computerized interview database using Access Runtime, which is freely available and compatible with all versions of Windows. The system will run on iOS but requires Windows and Office to be installed with Parallels or equivalent. The latest release of the UK 3Di software is compatible with Windows 10. A structured computer-generated report in Microsoft Word is available upon completion. All data are automatically downloadable into spreadsheet format. The software used to construct the interview has a number of features that were developed to enhance the user experience. These include the use of an “interviewer explorer” tree and colored tabs that indicate

whether a question has been answered or not. The interview tailors itself to the gender of the subject and the names of the child and parents. Alternative routes through the interview can be selected, which facilitate the efficient pre-entry of material such as demographic details of the family, as well as allowing specific routes to be selected in order to identify comorbidity. Furthermore, the interview consists of several modules. The standard interview asks about both potential ASD and attention deficit hyperactivity disorder (ADHD). Other modules, which are concerned with the full range of child psychiatric comorbidity, are optional. There are also questions about a range of adaptive functions, including motor skills, sleeping and eating, etc. Algorithms speed the interview by eliminating illogicalities, such as questions about spoken language in a nonverbal child.

The interviewer must make simple coding decisions in response to most questions, as it is a critically important aspect of the design that the interviewer interprets the interviewee's qualitative responses and makes coding decisions based on their clinical expertise. The wording, content, and coding of those questions have been designed to simplify, quicken, and ease the decision-making process. Responses about behaviors are generally coded on three point scales: with “0” indicating no such behavior is or has ever been present; “1” signifying minimal evidence of such behavior; and “2” representing that there is or has ever been definite or persistent evidence of such behavior. For the RRBI domain, a fourth option is often possible, which includes clear evidence of the behavior and clear impact on social functioning. Because coding options are simple and limited, it is possible for the interviewer to quickly verify with the respondent which option is the most appropriate. Moreover, some coding decisions are deliberately skewed (e.g., “often, rarely, never”), in order to magnify differences between populations and increase discriminant validity. The 3Di recognizes that asking parents to describe in detail specific behaviors their child may have demonstrated many years previously produces responses of unverifiable validity. Accordingly, the interview's emphasis is on coding current

behaviors for the most part. Selected questions about repetitive and stereotyped behaviors and sensory sensitivities seek evidence from early childhood onward because these aspects of the autism spectrum tend to ameliorate, especially in those with normal-range intelligence.

Training in the use of the interview can be provided and is brief. It entails role-playing, video rating of model interviews, and an introduction to the interview software (Ix Dx 2019). Interpretation of the DSM-5 algorithms and the interview's integration with observational assessments is covered. Inter-rater reliability for the "blind video rating" is ascertained after every course and is excellent ($kappa > 0.85$). Training courses are held worldwide, and over 2500 trainees are now using the 3Di in clinical practice.

Historical Background

The Developmental, Diagnostic and Dimensional interview was developed in the early 2000s by David Skuse et al. (2004), when changes in the conceptualization of autism as a multidimensional condition raised the need for new methodologies that could capture the severity of autistic traits in clinical as well as general population samples. Both inter-rater and test-retest reliability were potentially enhanced by the computerized format, compared with other autism assessment instruments. The computerization of diagnostic algorithms ensured diagnostic validity was maintained, and the potential to create a diagnostic database facilitated research. The range of questions incorporated allowed users to distinguish between ASD, specific language impairment (SLI), and other comorbidities.

While the original interview takes 2 h to complete, a short 45-min version (3Di-sv) has also been constructed (Santosh et al. 2009). This short version comprises 53 items in 3 domains: reciprocal social interaction (24 items), communication (21 items), and repetitive and stereotyped behavior (8 items). In addition, it originally included eight items concerning language development and age of first symptoms, which were to be used for DSM-IV-TR classification of PDD

subtypes. Concurrent validity with the full version is excellent, but the 3Di-sv was originally not compatible with DSM-5 as it emulates the ADI-R (DSM-IV TR) algorithm. Therefore, in the Netherlands, a study was performed to make the 3Di-sv compatible with DSM-5 (Slappendel et al. 2016). This 3Di DSM-5 short version is currently being further evaluated.

Recently, a version for adults of normal intelligence has been developed: the 3Di-Adult (Mandy et al. 2018). The 3Di-Adult can be administered to a parent or a relative of the client. The items were taken from an initial item pool from the diagnostic algorithm of the original 3Di (Skuse et al. 2004; Santosh et al. 2009), which have previously been identified as being especially discriminating. Subsequently, based on discussion within the study team, the items were matched to the DSM-5 criteria. Next, based on discussion and pilot analyses of existing 3Di data, the questions were sorted into those best suited for discriminating symptoms in either childhood or adulthood, which were then rephrased as either historical questions ($n = 21$) or to assess current behavior ($n = 31$). Lastly, 17 new questions were constructed based upon knowledge of the ASD phenotype in adulthood, to ensure that all aspects of the DSM-5 were covered. This process resulted in a 69-item version for adults. Preliminary analyses revealed high inter-rater reliability and internal consistency of the scales. Furthermore, substantially higher subscale scores for ASD cases than comparisons were found, demonstrating criterion validity. The 3Di-Adult was also highly accurate in discriminating between ASD cases and comparisons and was found to have excellent sensitivity (95%) and specificity (92%). The interview took 50 min for people with ASD on average. Although these findings are preliminary, the 3Di-Adult seems promising as a useful tool in research or clinical practice in identifying ASD in adults based on the DSM-5 criteria. The 3Di-Adult has also been translated into Dutch, in which language its validity is currently being investigated.

The 3Di has previously been translated into several languages: Dutch, Finnish, Italian, Norwegian, Spanish, Cantonese, Mandarin,

Taiwanese, and Thai, of which the latter four are currently only available in the short version. Other translations (e.g., Arabic, Hindi, Swahili, French) are still under development. In 2012, a validation study was published by the Thai translation team (Chuthapisith et al. 2012) in which a group of 63 children with clinically ascertained ASD was compared to a group of 67 typically developing children on their mean 3Di-sv scales scores in each of the 3 domains. The results showed similar sensitivity and specificity to the original UK sv-validation (Santosh et al. 2009). The highly detailed phenotyping that is possible with the 3Di allows one to examine subtle differences in the ASD phenotype that might be due to cultural factors. Considering the reformulation of ASD in the DSM-5, and the condition becoming an increasingly global diagnosis, a study was performed (Mandy et al. 2014) that investigated the DSM-5 version's applicability and cross-cultural stability across the spectrum of symptoms in two different cultures (i.e., UK and Finland). Using confirmatory factor analysis and comparison of model fit between Finnish and UK participants, it was found that the DSM-5 model worked well in ASD participants in both cultures. However, it was found not suitable for measuring the sub-clinical autistic trait characteristic of the broader autism phenotype (BAP) in the Finnish population. This finding might suggest that cross-cultural variability may be greatest for subtle differences in the ASD phenotype.

A study by Slappendel et al. (2016) investigated the items of the short version of the 3Di (3Di-sv; Santosh et al. 2009) which were translated into Dutch. Criterion validity was explored by first comparing the 3Di-sv classifications to clinical diagnoses that were confirmed by an ADOS-2 classification. Data were available for 146 children (50 of whom were considered to have ASD). Although the 3Di-sv classifications showed good sensitivity (.84), specificity was low (.54) when comparing with ADOS-2-confirmed clinical diagnosis. Post hoc analyses with the full sample ($n = 282$) were then conducted, which lacked some ADOS-2 data, but which better reflected the samples used in previous studies

that reported higher specificity for the 3Di-sv's performance (e.g., Chuthapisith et al. 2012). These resulted in a sensitivity of 0.77 and an improved specificity of 0.67. The researchers suggested the initial limited specificity they found, compared to previous studies, was due both to the stringency of their diagnostic criteria and to the clinical characteristics of their population.

Moreover, the PDD module of the 3Di was translated into Cantonese, and its applicability was subsequently tested using a sample of 194 Chinese children aged 6–12 years in Hong Kong (Lai et al. 2015). Using the original authors' cutoff scores, the Cantonese version was found to have excellent psychometric properties, a sensitivity of 95%, and a specificity of 77%. In distinguishing between ASD and non-ASD cases, the agreement was 85.6%, with κ 0.71. However, the relatively higher false-positive rate and relatively high scores on one of the PDD dimensions could be due to cultural differences between England and Hong Kong. For example, children in Hong Kong are less likely than British children to invite friends over after school. In these instances, higher 3Di scores do not indicate autistic symptoms but instead reflect the (social) cultural expectations, habits, and lifestyle of the people of Hong Kong. This finding highlights the need for further validation and development of norms for the 3Di in different cultural contexts.

The 3Di has been used in a wide variety of research studies. The detailed phenotyping generated by the interview has encouraged investigations of conceptual issues and more recently the construct validity of DSM-5 (e.g., Mandy et al. 2012a; Slappendel et al. 2016). Because the instrument seeks information about a wide range of associated symptoms, language development, and comorbidity, it has allowed researchers to employ the interview in studies on these topics. Furthermore, as trait measurement is quintessentially dimensional in character, the 3Di is also well suited for studies of the broader phenotype of ASC (e.g., De la Marche et al. 2015) and sex differences in the phenotype (Mandy et al. 2012b).

Psychometric Data

Reliability studies have been conducted in the development phase of the instrument, as well as “live” measures of reliability which were obtained during training courses. In the original reliability analyses (Skuse et al. 2004), all sections of the interview were administered to parents of 23 PDD and 27 non-PDD cases in a referral sample. The interview was performed by one member of the assessment team, while another scored the responses independently on a computer. Inter-rater and test-retest reliability were analyzed for ICD-10 diagnoses which are generated by the 3Di algorithms, resulting in 96% and 94% agreement, respectively. Intraclass correlation coefficients for both reliabilities were found in excess of 0.86, which is excellent. The reliability of the instrument during live training sessions has also been evaluated, when each group of trainees rates a video recording of an entire interview with the parent of an autistic child. Reliability was evaluated on the basis of ADI-R algorithm scores. For a consecutive training group of 208 psychiatrists, pediatricians, and other professionals, representing approximately 20 training courses, the reference score of the interviewer was compared to the group mean. For the reciprocal social interaction subscale, language and communication skills, and repetitive and stereotyped behaviors, the scores of the trainees were almost identical to the reference scores.

Extensive research on the 3Di has demonstrated its content, concurrent, discriminant, and criterion validity for ASD. The content validity was assessed (Skuse et al. 2004) by reviewing published material on significant discriminating behavioral characteristics in children with ASD as well as the diagnostic criteria as described in the DSM-IV (APA 2013) and ICD-10 (World Health Organization 1993). Concurrent validity of the 3Di with the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 2000) has been evaluated in both preschool and school-age children. Duvekot et al. (2015) found that the overall percent agreement between the 3Di and ADOS classification was 63%, with a $kappa$ of 0.20, indicating a slight agreement. However, as the

3Di and ADOS are different types of diagnostic methods (interview and observation), high agreement would not be expected. These instruments should nevertheless be complementary in the diagnostic process, to gain information from observation as well as parent report on current behavior and developmental history. Formal analysis of this aspect of validity is pending.

Furthermore, concurrent validity in autism spectrum conditions has been evaluated using a clinical sample of 60 children (Skuse et al. 2004). The diagnoses by a clinician on the basis of ICD-10 criteria and diagnoses on the basis of 3Di algorithms were compared, which showed that agreement between these methods was very good. Discriminant validity based on the 3Di algorithm's ability to distinguish between autistic and non-autistic conditions was found to be excellent, with a sensitivity of 1.0 and specificity being higher than 0.97. Furthermore, the 3Di's positive and negative predictive powers were found to be 0.93 and 0.91, respectively. The assessment of criterion validity was based on the assessment of 29 children with both the 3Di and the ADI-R, who had been interviewed on both instruments by different interviewers at two different points in time (a 2.4 years apart). Subscales that were similar in broad content and identical in the range of scores to the ADI-R were produced for the 3Di. The agreement on threshold for all three domains was found to be significant with $p < 0.01$, with 86% agreement in the reciprocal social interaction domain, 100% agreement for communication, and 76% for repetitive and stereotyped behaviors. However, complete agreement was not expected, in part because criterion validity was potentially compromised by inter-rater and test-retest variability and in part because the ADI-R algorithm was based largely on historical information, whereas the 3Di seeks contemporaneous information in virtually all domains.

Clinical Uses

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM; American Psychiatric Association 2013) and the International

Classification of Disease (ICD-10; World Health Organization 1993) are the current accepted classification systems for the diagnosis of ASD. The process of reaching an ASD diagnosis is complex, considering the etiological heterogeneity of ASD, high rates of comorbidity with other medical, psychological or psychiatric conditions, and different levels of severity in symptoms (Falkmer et al. 2013). Furthermore, diagnostic instruments should be highly sensitive and specific, in order to reduce the chances of false positives or negatives. Preferably, diagnostic instruments should also be brief and practical, as well as appropriate for all ages and IQ ranges within the autism spectrum (Mayes et al. 2009). Considering the 3Di's preliminary results indicating excellent reliability and sensitivity, high sensitivity, specificity, and correct classification rate, as well as its practical computerized use and option for the use of a short version, it has proven to be a valuable tool in the diagnostic process.

The current “gold standard” for diagnosis of ASD includes a standardized observation of the child, such as the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 2000) and a standard parental interview, for example, the Autism Diagnostic Interview-Revised (ADI-R; Lord et al. 1994) or the Developmental, Dimensional and Diagnostic Interview (3Di; Skuse et al. 2004) (Duvekot et al. 2015). In addition, according to the National Institute for Health and Care Excellence (NICE 2019), the true “gold-standard” clinical assessment should be a multidisciplinary team process which also involves other assessments with consensus clinical judgment such as differential diagnosis, a physical examination, and assessment of comorbid conditions. In a systematic literature review on diagnostic instruments assessing ASD by Falkmer et al. (2013), the 3Di was noted to have the highest correct classification rates of all tools evaluated. However, there are relatively few studies that provide evidence of its utility. Therefore, more research is needed on the 3Di in this regard.

The 3Di was originally devised to be a dimensional measure of autistic traits, although the disorder was predominantly conceptualized in categorical terms at that point in time. Accordingly, it was designed to emulate the algorithmic

content of the ADI-R (Lord et al. 1994), and as such, the 3Di's algorithm agreement with the ADI-R for threshold scores is high (Skuse et al. 2004). Furthermore, the 3Di was meant to also measure symptoms in a far broader context, including associated problems such as sensory sensitivities and pragmatic language skills, which were not at that time part of any diagnostic rubric, thus being wider in scope. The latest release of the 3Di-5 also includes a comorbidities tool, that screens for additional disorders based on DSM-5 diagnostic criteria. Algorithms generate comorbidity risks for all common child diagnoses. If full pre-entry has been achieved, it will be possible without further questioning – upon completion of the interview – to generate comorbidity probabilities for ADHD, conduct disorder, and tic disorders as well as pervasive developmental disorders. Additional modules allow the measurement of anxiety disorders, depression, dysthymia, bipolar affective disorder, eating disorders, post-traumatic stress disorder, and schizotypal disorders. However, it is important to note that the modules of this screening tool have not yet been validated, except for the ADHD module (which is mandatory because of the high overlap of symptoms with ASD), and the anorexia module has a solid foundation of expert input.

When the DSM-5 was published (APA 2013), the new diagnostic criteria were incorporated into a revised 3Di by writing new questions and developing new algorithms which mapped onto the DSM-5 criteria A and B. These included nonverbal interaction, peer relationships, sharing, socio-emotional reciprocity, nonverbal communication skills, conversational abilities, unusual preoccupations, routines and rituals, stereotyped and repetitive motor behavior, preoccupation with parts of objects, and sensory abnormalities. In the revised version, 108 questions contribute to the A-scale and 74 questions to the B-scale DSM-5 diagnostic algorithms. Mandy et al. (2012a) performed confirmatory factor analysis to assess the construct validity of ASD, especially its bidimensional reconceptualization of the autism phenotype. It was found that the two-factor model of autistic symptoms as described in the DSM-5 had superior statistical properties to the

DSM-IV-TR model. The results also showed that it made statistical sense to include stereotyped language usage (a subscale of the Children's Communication Checklist) within the restricted repetitive behavior dimension, together with the newly developed sensory abnormality symptoms. The latest release of the 3Di-5 (available upon request) has greatly increased the number of questions within this latter dimension (especially in the domain hyper- and hyposensitivity to a range of environmental stimuli), which has improved its metrical properties. However, although the 3Di output is tabulated in DSM-5 compatible form, the interpretation of that output has not yet been validated. To explore the compatibility of the 3Di-sv with the DSM-5, Slappendel et al. (2016) performed a study to investigate whether the short version of the Dutch 3Di translation (3Di-sv) would fit the DSM-5's two-factor structure as well as the three-factor structure of the DSM-IV-TR. Confirmatory factor analyses revealed a better fit for a DSM-5 model than DSM-IV-TR model of ASD. As exploration of the content validity for the DSM-5 revealed some construct underrepresentation, thus a panel of 3Di-trained clinicians suggested 14 items be added to improve the 3Di-sv construct, based on a theory-driven, face validity perspective. These suggestions included questions on the topics of insistence of sameness, adherence to routines, and sensory hyper- and hypo reactivity.

For future research, in order to create a new DSM-5 (short) version of the 3Di, adjustments need to be made and subsequently examined thoroughly. As current scoring algorithms still lead to DSM-IV-TR domains, specific DSM-5 3Di algorithms need to be validated and applied in sufficiently large samples and tested in clinical settings in order to achieve a full test of the construct validity of ASD. For example, versions including items that were added to provide better coverage of newly introduced DSM-5 criteria need further validation. Therefore, data-driven research on the suggested items on the basis of clinical consensus by Slappendel et al. (2016) is currently pending. This type of research should also consider evaluating the validity of the novel DSM-5 diagnosis of Social Communication Disorder, which is generated by 3Di algorithms. This diagnosis may apply

to children who were formerly diagnosed by DSM-IV TR with Asperger's disorder or PDD-NOS. Concern has been expressed that they may not fulfil the new DSM-5 criteria for ASD, which might subsequently lead to loss of eligibility for care (McPartland et al. 2012). Furthermore, translation and validation of the 3Di-Adult in other cultures will provide a reliable, valid, and resource-efficient way in helping the "lost generation" of adults with ASD who are currently lacking a formal diagnosis and therefore appropriate treatment (Mandy et al. 2018).

Short Description or Definition

One of the most common genomic syndromes involving multiple anomalies is Chromosome 22q11.2 deletion syndrome. Although there are earlier mentions of the disorder clinically, going back to 1829 (Greenberg 1993), the syndrome was first exemplified in detail by Angelo DiGeorge in 1968 (DiGeorge 1968) and by R. J. Shprintzen and colleagues in 1978 (Shprintzen et al. 1978); all presented children demonstrated clinical abnormalities such as underactive parathyroid gland, underdeveloped thymus, palate defects, facial anomalies, heart defects, and cognitive limitations. In the 1970s, the syndrome was also noted by Kinouchi et al. (1976), who labeled the condition as conotruncal anomaly face syndrome. Ultimately, in the 1990s, the specific genetic cause for the condition was identified as a microdeletion (i.e., a deletion of a part of a chromosome) of chromosome 22 at band q11.2 (Scambler et al. 1992). Thus, over the years, this genomic disorder has been called Sedlackova syndrome, DiGeorge syndrome, Shprintzen syndrome, conotruncal anomaly face syndrome, and velocardiofacial syndrome (VCFS). Since the 1990s, the syndrome has been increasingly referred to as 22q11.2 deletion syndrome, 22q11.2DS, which was used as an umbrella term to describe various clinical phenotypes originating from the deletion.

The 22q11.2DS is associated with a vast array of physical, medical, cognitive, behavioral, and psychiatric features. It is characterized by multiple (>180) developmental aberrations, including specific craniofacial features (cleft palate, velopharyngeal insufficiency; 69–100%), thymic and parathyroid defects including hypocalcemia (17–60%), congenital cardiovascular malformations (49–83%), and mild to moderate renal anomalies (36–37%). The most striking feature of the syndrome is the tremendous degree of phenotypic variability, both at the levels of the brain and behavior (Bassett et al. 2011; Kobrynski and Sullivan 2007; Roizen et al. 2007; Wang et al. 1998).

The associated phenotypes range from combinations of serious anomalies to the presence of

isolated mild impairments (McDonald-McGinn and Zackai 2008). Another central feature of the syndrome is the prominent presence of psychopathology (9–50%), with the most frequently observed conditions being developmental delay in infancy (75%) and childhood (45%), speech and language disorders (79–84%), schizophrenia spectrum disorders (1.9–41.7%), autism spectrum disorders (16–26.5%), attention deficit hyperactivity disorder (15–37%), and learning disabilities (50–80%) (Kobrynski and Sullivan 2007; McDonald-McGinn et al. 1999; Polleux and Lauder 2004; Prasad et al. 2008; Ryan et al. 1997; Schneider et al. 2014).

In addition, there are pronounced transformations of the syndrome's presentation across different developmental stages. The causes of such variability within the group of individuals with 22q11.2DS and across the life span within an individual are unclear (Aggarwal and Morrow 2008; Schneider et al. 2014). One of the most consistent findings in the phenotypic presentation of 22q11.2DS is a low average to borderline range of general cognitive functioning (Antshel et al. 2008). Yet, this deficiency is not consistent across different domains of cognitive functioning, although, as a group, individuals with the syndrome tend to function at a lower level than typically developing individuals in all domains of cognitive performance. Verbal functioning in spoken and written domains (e.g., receptive language, decoding and spelling, auditory verbal rote memory, but not higher-level processing such as comprehension) has been observed to be a relative strength, whereas visual-spatial (e.g., space orientation, visuospatial memory, visuospatial perception), quantitative processing (e.g., number and magnitude representation), and executive functioning (e.g., initiation, planning, working memory, and monitoring skills) have been marked as domains of particular weakness. Yet, once again, although this profile appears to be characteristic of individuals with 22q11.2DS as a group, within this group, there is variation in both the direction (i.e., reversed cognitive patterns have been reported) and the magnitude (i.e., the standard scores) of the discrepancy. Of note, data from a collaborative study by the International 22q11.2

Brain Behavior Consortium (Vrotsman et al. 2015) revealed that individuals with the syndrome show a cognitive decline of 7.04 Full Scale IQ points, 9.02 points in Verbal IQ, and 5.09 points in Performance IQ. Additionally, those individuals with a psychotic spectrum disorder experienced even more steeper declines in cognitive functioning.

Epidemiology

Chromosome 22q11.2DS is the most common microdeletion syndrome in humans, with prevalence estimates ranging from one in 2,000 to one in 6,395; with only 5–10% of deletions having been inherited and the rest arising *de novo* (Swillen et al. 1998). However, because many children born with the condition do not have observable abnormalities or immediately detectable medical difficulties, it has been suggested that up to one third of children are not diagnosed until later childhood and that some cases may go completely undetected. Therefore, the population prevalence may be closer to affecting 1 in 2,000–4,000 live births (Schneider et al. 2014; Shprintzen 2008). Boys and girls are affected equally, but the deletion is more prevalent within certain ethnic groups; 22q11.2DS occurs more frequently among Hispanics compared with Whites, African Americans, and Asians (Botto et al. 2003).

Natural History, Prognostic Factors, and Outcomes

Studies have demonstrated that heart defects and severe immune deficiency are the main causes of death in infants with 22q11.2DS. However, with the advancements in neonatal cardiology, many infants undergo early surgical repairs that permit them to survive. Currently, there is limited information regarding the life span of individuals with 22q11.2DS. There are regional data that suggest that if individuals receive adequate medical interventions or do not develop significant medical conditions, then the life span may be normative

(Shprintzen 2008). Similarly, psychological, psychiatric, functional, and vocational outcomes are likely influenced by a host of risk and protective factors, including: the size of the genetic deletion, genes in the region, the number of medical problems, presence of intellectual disability, and co-morbid psychiatric conditions, as well as family and environmental factors such as access to specialized educational and therapeutic interventions (Swillen et al. 2018).

Clinical Expression and Pathophysiology

Clinical Expression

The clinical expression of 22q11.2DS is extremely variable. Common phenotypic presentations may include the following: craniofacial abnormalities (cleft lip, cleft palate, velopharyngeal insufficiency, and microcephaly), feeding difficulties, conotruncal heart defects (tetralogy of Fallot, interrupted aortic arch, and ventricular septal defects), hearing loss or abnormal ear exams, genitourinary anomalies (absent or malformed kidneys), hypocalcemia (low blood calcium), and immunological difficulties due to abnormal T-cells. The facial features of children may also be atypical and may include the following: small ears, hooded eyelids, asymmetric crying facies, and small mouth, chin, and nasal area (Velo-Cardio-Facial Syndrome Educational Inc. 2009). In addition to these various medical vulnerabilities, individuals with 22q11.2DS frequently demonstrate a range of cognitive impairments. Typically, individuals exhibit low average to borderline intellectual functioning. Intellectual disability, typically in the mild range, has been documented in 25–40% of individuals (Shprintzen 2000; Swillen et al. 1997). In early childhood, infants and toddlers typically present with global developmental delays, including speech and language disorders. Later in childhood, specific patterns of cognitive and learning difficulties may become evident. Specifically, relative strengths in rote verbal memory, reading decoding, and spelling have been noted, in contrast to relative weaknesses in visuospatial memory, math computation, and executive functioning

(planning, cognitive flexibility, and working memory) (Simon et al. 2005).

Numerous psychiatric conditions have been reported to occur in individuals with 22q11.2DS. Accordingly, elevated rates of attention deficit hyperactivity disorder (ADHD), anxiety disorders, major depression, obsessive compulsive disorder, and oppositional-defiant disorder have been observed in clinical samples (Antshel et al. 2006). In late adolescence and early adulthood, even more debilitating psychiatric conditions may emerge, such as those characterized by psychotic symptoms, including schizophrenia and schizoaffective disorder. Gothelf et al. (2009) initially suggested that up to one third of patients may acquire psychotic disorders. Yet data from the International Consortium on 22q11.2 indicate that the rates of psychotic disorders vary across age groups, ranging from 1.97% in childhood to 10.2% in adolescence, and 41.3% in mature adults (Schneider et al. 2014).

There have been numerous investigators who have concluded that autism spectrum disorders can be quite prevalent in individuals with 22q11.2DS, with rates ranging from 12% to 50% (Antshel et al. 2007; Chudley et al. 1998; Fine et al. 2005; Niklasson et al. 2001; Schneider et al. 2014; Vorstman et al. 2006). Investigators have also examined how the social deficits observed in children with combined 22q11.2DS and autism are the same or different than children with just autism. There are researchers that have proposed that autism in 22q11.2DS may be qualitatively quite different from idiopathic autism. Specifically, children with combined 22q11.2DS and ASD may have less joint attention, lower levels of make-believe play, and higher levels of repetitive behaviors than those with 22q11.2DS alone (Eliez 2007; Tang et al. 2015). Thus, there is a consensus that children with 22q11.2DS should receive routine, standardized assessments for autism. Furthermore, early assessment for more serious psychopathology such as schizophrenia should also be conducted with children.

Genetics

The pathogenesis of 22q11.2DS is understood relatively well (Grigorenko et al. 2010). Most

cases of 22q11.2DS occur in the general population sporadically, or by chance, but only a portion of cases are inherited as an autosomal dominant trait (Swillen et al. 1998). The syndrome's molecular mechanism is well studied on the cytogenetic level (i.e., at a resolution of hundreds of thousands of bp); the deleted material can range from the more commonly seen 3 Mb deletion (~90%) to the less commonly seen 1.5 Mb deletion (~7%), with the rest having an even smaller deletion with an undetermined minimal size. Deletions in individuals with 22q11.2DS are more frequently of maternal than paternal origin, 56% versus 44% (Hacıhamdioğlu et al. 2015). There appears to be no association between the parental age and the frequency of the deletion (Delio et al. 2013). The pericentromeric region of chromosome 22q, and in particular 22q11, is rich in regions of segmental duplication (SD). SD regions are stretches of the human genome that have one or several highly sequence-homologous (i.e., more than 90% of identical sequence) counterpart(s) elsewhere in the genome, either upstream or downstream on the same chromosome but also on other chromosomes. Such SDs are frequently associated with variability in copy number, even in the normal genome of healthy individuals, as well as with the formation of aberrations leading to genomic disease. In 22q11.2DS, the 3 Mb typical deletion has both of its breakpoints in prominent SD regions. Also, most of the subtypical or atypical deletions have at least one of their endpoints in one such segmentally duplicated stretch of 22q11. The 3 Mb deletion region affects approximately 50 genes and 7 micro-RNAs, whereas the 1.5 Mb region 24 genes. The diminished dose of these genes, or their haploinsufficiency, likely compromises early morphogenesis of the organs impacted by the syndrome. Based on the research in mouse models, however, it appears that no single 22q11.2 deletion region is both necessary and sufficient for the expression of the major features of the syndrome (Amati et al. 2007). Similarly, there appears to be no difference in the clinical severity of the disorder depending on the size of the deletion. Only specific facets of the general clinical manifestation of 22q11.2DS have been understood so far. For example,

malformations of the heart and outflow tracts, as well as facial dysmorphism, palatal defects, hypoplasia of the parathyroid glands and thymus, and dental, feeding, and swallowing problems in individuals with 22q11.2DS are believed to be associated with haploinsufficiency for the *TBX1* (T-box-containing transcription factor 1) gene (Lindsay et al. 1999; Scambler 2010). However, other facets of 22q11.2DS remain etiological puzzles. For example, it is assumed that the syndrome and its psychiatric facets are associated with one or more candidate genes in the deleted region (Prasad et al. 2008). Specifically, among these genes are *COMT* (the gene encoding catechol-O-methyl transferase), *PRODH* (the gene coding for proline dehydrogenase), *GNBIL* (a gene that encodes a protein of unknown function), *ZDHHC8* (the gene coding for zinc finger and DHHC domain-containing protein 8), and *ARVCF* (the armadillo repeat gene deleted in 22q11.2DS, which may have a role in cell-to-cell communication and intracellular transduction during embryonic development). Yet, the results of studies of these candidate genes are provocative, but inconclusive. Similar to the role of *TBX1*, it is possible that haploinsufficiency in specific other genes results in specific features of 22q11.2DS (Meechan et al. 2007). Thus, haploinsufficiency for *GP1BB* might contribute to the mild thrombocytopenia seen in patients, and haploinsufficiency for *COMT* might contribute to cognitive aspects of the 22q11.2DS phenotype (Kobrynski and Sullivan 2007). The genes lost in 22q11.2DS, *PRODH*, *TBX1*, *GNBIL*, *COMT*, *ARVCF*, *DGCR8*, *RANBP1*, *ZDHHC8*, and *PIK4CA*, are located in or relatively close to regions of SD. Each of these genes or a combination of them might contribute to the etiology of the syndrome. However, with the genomic technology that is now allowing high-resolution analyses (i.e., with a resolution of just a few 100 bp and even down to the level of a single bp, in contrast with conventional cytogenetic analyses that have a resolution no better than several tens of thousands and often as many as hundreds of thousands of bp), the picture is changing dramatically. There is a variety of deletions found in chromosome 22q11.2 that are largely submicroscopic, have a

recognizable but often variable phenotype, and show recurrent breakpoints in unrelated individuals (McDonald-McGinn et al. 2015).

Evaluation and Differential Diagnosis

When 22q11.2DS is suspected by a physician (most often due to the presence of heart defects, clefting, facial anomalies, hypocalcemia, or absent thymus), then the most reliable diagnostic tool is a blood test in which the deletion in chromosome 22q11.2 region is detected through the FISH test (Fluorescence In Situ Hybridization in Situ Hybridization) or by other higher-resolution molecular techniques. If no deletion is found in this specific region of the chromosome, then additional chromosomal studies may be conducted to determine whether other types of chromosomal disorders might be present. Once the diagnosis of 22q11.2DS has been made in a child, then typically the parents are encouraged to take the FISH test so that it might be determined whether the child's condition was inherited (Velo-Cardio-Facial Syndrome Educational Inc., 2009). Within the psychological domain, given the preponderance of early developmental delays (language disorders, intellectual disability, and learning disabilities) in addition to the possible emergence of significant behavioral (ADHD), psychiatric (anxiety, depression, and psychosis), and social difficulties (autism), it becomes critical for patients with 22q11.2DS to have repeated comprehensive developmental and neuropsychiatric assessments across the life span.

Treatment

Due to the highly varied needs of children and adolescents with 22q11.2DS, treatment approaches by necessity can be quite complex and multidisciplinary (Shprintzen 2008). The International 22q11.2DS Consortium (Bassett et al. 2011) has developed a range of "Practical Guidelines" for the management of patients with 22q11.2DS which takes into account the multi-systemic nature of the disorder and the varied

clinical considerations across the lifespan. Accordingly, common medical difficulties such as cardiac malformations or heart disease are managed through surgical interventions, and cleft palate repairs can be effectively resolved through palate repair. Similarly, severe feeding difficulties can be temporarily addressed through gastrostomy, but are most often remediated through behavioral feeding programs. For infants and toddlers with early developmental delays, including poor muscle tone and delayed speech, then referrals for early stimulation programs become critical. In later childhood, children with 22q11.2DS may require a range of special education services including speech and language therapy, occupational therapy, physical therapy, learning disabilities instruction, and even specialized school placements. Finally, as discussed, due to the high rates of behavioral and psychiatric conditions in children with 22q11.2DS, early evaluation is warranted through use of standardized instruments and structured observations. Pharmacological interventions to treat ADHD, mood disorders, and psychotic symptoms have been increasingly utilized with patients with 22q11.2DS (Shprintzen 2008), in addition to a range of evidence-based behavioral and cognitive behavioral treatments (Tang et al. 2015) such as cognitive remediation training, applied behavioral analysis, social skills training, CBT for anxiety and depression, and parent training programs.

Developmentally Appropriate Practice

► Normalization

Developmentally Appropriate Practice (DAP)

Ilene Sharon Schwartz¹ and Bonnie McBride²

¹Haring Center for Applied Research and Training in Education, University of Washington, Seattle, WA, USA

²Intervention Services for Autism, University of Oklahoma College of Medicine, Oklahoma City, OK, USA

Synonyms

Chronological age appropriateness; Individual appropriates; Intervention targets and strategies that are related to increased quality of life outcomes

Definition

Developmentally appropriate practice (DAP) refers to providing intervention in a manner that is individually appropriate and culturally relevant for the learner. This term was first introduced by Sue Bredekamp and the National Association for

the Education of Young Children (NAEYC) in 1987 to warn early educators against the trend of pushing typically developing or gifted children too far too fast, or what some developmental psychologists referred to as “robbing children of their childhood” with deleterious effects that may not show up until adolescence or later. It also has important implications for working with students who have cognitive deficits so that families and interventionists interact with people in a manner that is age appropriate and provide opportunities to people that are both age appropriate and matched with individual strengths and preferences.

This concept of DAP is important when planning and implementing interventions for people with ASD. Developmentally appropriate interventions are those that take the student’s chronological as well as developmental age into consideration when identifying targets, materials, places, and strategies for intervention. Interventions that are developmentally appropriate also consider issues of cultural relevance and attempt to insure that the behaviors and skills selected as intervention targets are related to improving the quality of life for the person with ASD and his/her family.

Developmental-Pragmatic Approaches/Strategies

Sima Gerber

Department of Linguistics and Communication Disorders, Queens College, Flushing, NY, USA

Definition

Developmental-pragmatic approaches to language intervention have a dual focus: (1) generating treatment goals and procedures based on the child's stage of development as determined by what is known about typical trajectories and (2) generating treatment goals and procedures based on the tenets of social-pragmatic perspectives on language acquisition and use. The child's developmental stage, rather than his or her chronological age, is considered not only in reference to language but also in reference to those areas of development thought to be precursors and cocursors of language, such as symbolic-cognitive (e.g., play abilities) and social-emotional functioning (e.g., interacting with others). Three tenets of social-pragmatic models of language acquisition serve as the foundation for language intervention which is derived from this thinking: (1) language develops within the context of the caregiver-child relationship, with an attuned and loving partner; (2) early developments in engagement, intentionality, and communication set the stage for the ability to comprehend and produce language; and (3) the use of language includes the capacity to know when to say what to whom.

Historical Background

The field of speech-language pathology was dramatically impacted by the introduction of social-pragmatic models of language acquisition in the 1970s and early 1980s (Bates 1976; Bates et al. 1975; Bruner 1975, 1977; Dore 1975; Halliday 1975; Prutting 1982). With these models, the world of communication disorders began to reconsider fundamental questions, such as what defines a language user and how does a language disorder compromise these capacities. Interest in constructs such as intentionality, nonlinguistic communication, functions of language, social interaction, contexts of language learning and language use, discourse, and conversational skills represented a departure from earlier thinking in both language acquisition and language intervention. Taxonomies from the world of typical social-pragmatic development began to appear in language assessment protocols and intervention plans for children with autism spectrum disorders. These included taxonomies of prelinguistic development (communicative intentions), speech acts and functions of language (labels, comments, requests, greetings, etc.), and conversational analysis (initiating and maintaining topics, turn-taking, and contingency). These paradigms were immediately of interest to speech-language pathologists (SLPs) working with children with autism spectrum disorders because for the first time, the nature of these children's language and communication challenges was more adequately described and understood.

Once the breadth of pragmatic models of language acquisition and language use were integrated into the world of communication disorders, the work of speech-language pathologists expanded to include new dimensions of typical language development and language use and greater attention to the contexts of language learning and language use. The earlier "semantic revolution" which brought us from "form" (i.e., the structure of language) to "content" (i.e., the meanings of language) led quite quickly to a "pragmatic revolution" which required professionals to once again rethink the nature and the boundaries of their work as they added a third component to

the definition of language, namely, “use.” Perhaps as important was the shift in thinking about the role of the SLP, from the teacher of language to the partner in the language acquisition process. Encouraging the child’s initiation and intentionality was seen as more important than obtaining responses from the child. Finally, the notion of therapy contexts expanded to potentially include all the contexts of the child’s life, from home to school to play, with a variety of partners, both in terms of number and age (from one adult to groups of peers).

The focus on the interpersonal functions of language was particularly attractive to clinicians who were working with children who could talk but did not use language appropriately for the typical range of communicative intentions (commenting, reporting, requesting answers). In fact, the new taxonomies provided ways of understanding the unconventional linguistic patterns used by some children on the autism spectrum. Prizant and Duchan (1981) noted that children with autism were often expressing typical functions of language with echolalic utterances. Obviously, the relationship between form and function was idiosyncratic (e.g., the child says “Do you want a drink?” to indicate that he or she wants a drink), but nonetheless, the utterances were intentional and certainly could not be simply discounted as inappropriate. The “discovery” that echolalic language was intentional led to shifts in intervention procedures from those which suggested ignoring or discouraging echolalia to those that honored it. The primacy of function over form, a direct outgrowth of pragmatic models, was a theme that resonated with SLPs who were working with children who were nonverbal (e.g., standing in the corner to communicate anxiety) and/or using unconventional means of communication (e.g., repetitively asking questions to deal with transitions).

Although the impact of developmental-pragmatic models of language acquisition had a lasting effect on language assessment and intervention with both children and adults with a range of language disorders, many would agree that speech and language intervention with children with autism spectrum disorders was particularly

effected by embracing this model. The nature and breadth of pragmatic views of language spoke directly to the nature and breadth of the children’s challenges, providing new directions for SLPs working with this group of children.

Rationale or Underlying Theory

A developmental-pragmatic model (DPM) rests on the universals, processes, and facts of typical language acquisition. This information clarifies what is learned by a typically developing child at each point in development, resulting in the child’s acquisition of a symbolic language system and his or her success as a social communicator. The speech-language pathologist who embeds his or her thinking in this theory believes that the language acquisition of children on the autism spectrum includes both typical and atypical parameters, all of which are best understood by reference to the universals of speech, language, and communication development.

Developmental-pragmatic models of language intervention pay particular attention to the social underpinnings of language acquisition and use. While encompassing the interest in the form of language (phonology, morphology, and syntax) and the content of language (semantics), pragmatic thinking leads us to consider the broader interpersonal context of language acquisition and the early ability of the communicator to use gestures, facial expressions, and words for social interaction purposes. Thus, the emphasis on context, both of language learning (i.e., caretaker-child interactions) and language use (e.g., how the intent of our utterances is understood depending on who is being spoken to, what the setting is, and the knowledge of the participants), is considered developmentally from birth to adulthood. The fact that some children on the autism spectrum have strengths in form and content with considerable deficits in pragmatics speaks to the components of language necessary to be a successful and conventional language user.

Regardless of the specific discipline, developmental approaches begin with the assumption that all strategies of intervention, regardless of the

target group or desired outcome, can be derived from normative theories of development. That is to say, the general principles of development apply to all children independent of their biological variability or the range of environments in which they live (National Research Council and Institute of Medicine 2000). We might add to this that goals of intervention can best be derived from normative theories of development as well and that this is particularly compelling when considering children with deficits in social-pragmatic aspects of language.

This overarching understanding of developmental approaches paired with the specifics of pragmatic thinking served as a rich resource for recasting the assessment and intervention of children on the autism spectrum. The emphasis in pragmatic approaches on the intersect between the capacity to interact and the capacity to comprehend and produce language immediately resonated with the challenges and needs of children on the autism spectrum. The models presented in the literature by Bates et al. (1975); Dore (1974, 1975); Halliday (1975); Bloom et al. (1976); Snow (1973, 1978); etc., offered the theory and frameworks for reconsidering what and how we were teaching children with autism spectrum disorders to learn and use language. SLPs began to use and adapt the taxonomies which appeared in the research literature on topics such as the speech acts expressed by young children using single words, the early development of conversational skills, and the nature of adult input to language-learning youngsters.

As this movement continued and moved more deeply into the world of joint attention, early relationships, and affective range (Tomasello 1988; Greenspan and Wieder 1998; Mundy and Sigman 2006), speech-language pathologists continued to integrate the expanding theory into their work with children with challenges (Prizant et al. 2006). More and more intervention programs began to address the social engagement issues of children on the autism spectrum, and, in fact, approaches which differed considerably in the strategies and contexts of intervention now share the emphasis on interaction, reciprocity, and shared attention. The fact that typically

developing infants can easily participate in attuned, communicative exchanges and that children with autism spectrum disorders find this developmental step so challenging is a universal concern in the educational and therapeutic planning for children on the autism spectrum.

Once again, while many of the pragmatic constructs speak to the process of language acquisition and, thus, are relevant for intervention programs for all children with delays and disorders in speech and language development, the nature of autism spectrum disorders has led to a particular interest in this body of work.

The following list of principles reflect the underlying theory of a developmental-pragmatic model of language intervention (Gerber 2003) and are thought to serve as the basis for and rationale for intervention goals and procedures:

- Language is learned in the context of spontaneous, natural everyday interactions between the caregiver and the child.
- The child's language acquisition is embedded in his or her cognitive, affective, and social development and life.
- The development of communicative intentionality precedes the development of language.
- Prelinguistic developments in cognitive, social, emotional, and communicative domains precede the comprehension and production of language.
- The child's communicative interactions include many opportunities to play speaker-initiator and listener-responder discourse roles.
- Both typically and many atypically developing children move through the same general stages of linguistic and communicative development.
- The specifics of language development (e.g., rate, style, strengths) are characterized by individual variation.
- Imitation may play a role in language learning for some children; its role in the development of communication is generally recognized.
- The child plays an active role in his or her language development – meaningful and joyful interactions with the world of objects and the world of people serve as the context for the development of language.

Goals and Objectives

Operationalizing developmental-pragmatic goals and objectives can be thought of in a number of ways, all of which differ from traditional perspectives on how to view the basic components of language intervention. These components include what the goals of intervention are, who the participants are during intervention, what procedures should be used, where the therapy takes place, and what role the adult plays during the interaction. A continuous thread from paradigms of assessment to paradigms of intervention are characteristic of language intervention programs which are based on developmental social-pragmatic theories of language acquisition (Gerber and Prizant 2000; Prutting and Kirschner 1987).

One of the most significant impacts of pragmatic models on the world of language disorders was the rethinking of the intervention goals addressed with children who had challenges in the acquisition of speech, language, and communication. The fact that nonverbal communication including gestures, facial expression, body language, and vocalizations were now considered appropriate goals of intervention represented one significant departure from earlier views which focused on the production of words and sentences. For those children who had not yet developed the capacity to communicate through nonlinguistic forms, the importance of that step in the developmental trajectory on the way to language was more fully recognized. In fact, the notion that nonlinguistic communication continues to be a goal of therapy even for children who are verbal was welcomed by clinicians who were working with children on the autism spectrum who could talk but did not use pointing and showing, eye gaze, and intonation to communicate their intentions.

Further, for children who are at very early developmental stages, pragmatic goals address the social-emotional precursors to language. These include increasing engagement in back and forth adult-child interactions; facilitating affective exchanges between the adult and the child using nonlinguistic communicative forms;

increasing periods of joint attention with caregivers; communicating a range of intentions using differentiated vocalizations, pointing, eye gaze, and word approximations; and facilitating social referencing. Of course, precursory goals related to the content of language and the form of language would also be a part of every child's intervention plan. At these early stages, goals for the caregivers include increasing their responsiveness to the child's potentially communicative attempts and fostering reciprocal interactions, using the child's current repertoire of behaviors.

Of particular relevance for children with autism spectrum disorders was the notion of intentional communication and functions of language which moved to center stage in language intervention as a result of the understanding of pragmatic models of language development. The fact that this group of children did not use their non-linguistic or linguistic systems to communicate a range of intentions had been documented in the research and confirmed by clinical experience. Thus, rather than moving on to the development of larger vocabularies and longer sentences, clinicians began to facilitate the use of the children's existing systems for functions beyond requests, such as greetings, comments, and social routines. The idea that children needed to acquire not only the forms of language but also the interpersonal functions led to an expansion of goals and objectives that has had considerable longevity.

For children whose nonlinguistic and linguistic systems are somewhat unconventional, intervention goals begin with an attempt to analyze the form-function relationship in that child's system. One finding from this type of analysis has been that a child who does not use conventional language may very well be communicating intentions. Unconventional behaviors, echolalia, delayed echolalia, and scripts are often attempts to initiate conversation and/or to communicate particular functions and meanings of language. In terms of a less conventional nonlinguistic system, if a child's tendency to put his or her face close to that of another person is seen as an attempt to start an interaction, the function of the behavior can be acknowledged while more conventional forms are modeled ("let's play").

Responding in this way to a child's behaviors, with an eye toward the function they may serve, came from the focus on function in the pragmatic analysis of language and communication. Similarly, when working with a child who was using a less conventional linguistic system, clinicians began to understand the importance of imbuing the child's echolalic utterances and scripting with communicative intent. This response to the child turns a somewhat ambiguous communicative moment into a productive one and again illustrates how goals informed by pragmatic thinking were drastically different from more traditional ones.

Developmental-pragmatic goals are determined by assessing the child's developmental stage of language acquisition and strengths and challenges in social-pragmatic domains of development. Some examples of typical developmental-pragmatic goals for children functioning at earlier stages of development might include the following, written from the perspective of what the SLP will focus on:

- To facilitate the child's interpersonal engagement and emotional range (e.g., happy, sad, curious, frustrated, angry), with nonlinguistic and/or linguistic forms of communication
- To facilitate the child's participation in joint attention interactions with an adult, with nonlinguistic and/or linguistic forms of communication
- To facilitate the child's range of communicative intentions, with nonlinguistic and/or linguistic forms of communication
- To facilitate the use of spontaneous, self-initiated communication, with nonlinguistic and/or linguistic forms
- To expand the range of forms used to communicate, including both nonlinguistic forms (gestures, signs, visual systems) and linguistic forms (vocalizations, intonation patterns, words, utterances)
- To facilitate the use of social referencing, with nonlinguistic and/or linguistic forms of communication
- To facilitate the child's intention to communicate in a range of naturalistic contexts

(at home, on the playground, with adults, with peers)

- To respond to all of the child's attempts to communicate whether they are conventional or unconventional

For children at higher developmental stages of language, typical developmental-pragmatic goals might include:

- To facilitate participation in conversational exchanges, playing both the speaker and the listener roles
- To facilitate the use of contingent responses during conversational exchanges
- To facilitate an understanding of the listener's perspective and the need to modify one's nonlinguistic and linguistic communication for a range of partners
- To facilitate the ability to repair communication breakdowns
- To facilitate peer interactions, first in dyadic interactions and eventually in larger groups
- To facilitate the coordination of conventional nonlinguistic and linguistic systems to communicate intentions

It should be noted that depending on the child's developmental stage of language, simultaneous goals addressing the comprehension and production of language would be included in an integrated plan of language intervention. Similarly, social-emotional, cognitive-symbolic, and regulation goals will necessarily be considered in all intervention plans that are addressing the further development of language and communication.

Treatment Participants

One of the most vivid and lasting effects of the pragmatic revolution on the field of speech and language was the change of thinking about who the treatment participants should be during intervention. Here, again, this notion had particular resonance for children on the autism spectrum because of the nature of their difficulties in interpersonal interactions.

With the early and continuing interest in pragmatic models and social-emotional approaches to working with children with developmental challenges, SLPs have been exposed to a deepened understanding of the nature of the caregiver-child relationship. This relationship sets the stage for the child's healthy development in all areas of functioning, including the development of the comprehension and production of language. SLPs began to think not only of *what* was learned in the prelinguistic period but *who* was propelling the development and why this relationship was key to the process. The notion that more of the "work" in language intervention should be done with the mother or primary caregiver and the child, rather than the therapist and the child, continues to be difficult to realize during intervention and, yet, is a clear implication of pragmatic models of language acquisition. Even in settings where it is easier to work with the caregiver, such as in early intervention conducted in the child's home, practitioners are not necessarily comfortable with the idea of "coaching" a parent during an interaction and, often, prefer to have the parent observe as the therapist interacts with the child. While understandable, this is not in sync with the research now spanning more than 30 years, suggesting that the caregiver-child interaction is where the "action" is relative to setting the stage for development.

Further, because pragmatic models of language acquisition underscore the fact that language use occurs across contexts with different partners, language intervention which has its roots in this model embraces the notion that the child's ability to use language must be addressed in a range of real-life situations, including his or her other interaction with family, teachers, and peers. Remembering that pragmatics refers to the ability to know what to say when to whom, pragmatic interventions go beyond the traditional therapy room and the SLP-child interaction. The child's interactions with typical and atypical peers must be built into the intervention planning. In fact, quite a few programs have been developed where typical peers coach their classmates who are on the

autism spectrum to enhance the possibility of more frequent and successful exchanges (Kohler et al. 2005).

Prior to the introduction of developmental-pragmatic models, the fact that a successful language user can communicate effectively with many different partners was not recognized as a potential language intervention goal. This notion led to one of the most significant shifts in the intervention paradigms of speech-language pathologists. Improving the child's ability to communicate with different partners requires the SLP to consider the child's interactions with every person in his or her life and to potentially use these interactions as the contexts for language therapy.

Treatment Procedures

The use of developmental-pragmatic models to generate treatment procedures requires an understanding of the way language acquisition progresses and language use is realized in authentic communicative contexts. As mentioned in the previous section, implications from a developmental-pragmatic model affect decisions about all the components of therapy, not only what the goals of intervention are and who the participants are during intervention but also what procedures will be used during treatment. In this discussion, intervention procedures include intervention strategies, intervention contexts, and the role of the adult during the interaction.

The following list captures the nature of *strategies* generated from developmental-pragmatic models of language use:

- Provide many opportunities to facilitate sustained engagement and reciprocal interactions, both nonlinguistically and linguistically.
- Provide many opportunities to expand shared attention and more consistent responsiveness to the communicative partner.
- Interpret all of the child's behaviors, conventional and unconventional, as intentional and meaningful.

- Maintain a reciprocal flow by treating all of the child's behaviors as communicative as you alternate turns in the interaction.
- Model the use of nonlinguistic and linguistic forms of communication to express the child's meanings, messages, and intentions, not yours.
- Engineer the context so that the child has an opportunity to play both initiator and responder roles in the "conversation."
- Engineer "turn-taking," by expectancy, waiting, and nonverbal communication.
- Teach language within the context of natural interactions and discourse.
- Embed language training in contexts that are familiar to the child relative to meaning and affectively laden.
- Reduce the complexity of your language input while maintaining the "grammar" of language, the melody, and the interactive flow of communication.
- Pair language with the child's actions, interests, agenda; timing and contextual support are critical at early stages of language learning.
- Join in the meaning and affective tone of the child's script.
- Teach language when the cognitive, social, affective, and pre- and/or corequisites are in place.
- Teach the child's parents, teachers, and therapists how best to facilitate language throughout the child's daily life.
- Teach language with words and silence.
- Teach language when the interaction is flowing.
- Teach language by matching and meeting the child and then "up the ante."
- Teach pragmatic skills within the context of natural conversation.
- Engineer natural opportunities for promoting nonverbal pragmatic abilities such as proxemics, body language, gestures, and facial expressions.

In reference to intervention *contexts*, pragmatic views of language suggest that all the contexts of a person's life are of interest when we are studying and supporting language use. Much like the idea of different partners, pragmatic models are rooted

in the idea of the range of contexts which make up the person's life and the variations in both non-linguistic (setting, activity, participants) and linguistic (prior discourse) aspects of each context. As a result, attempts were made to expand the notion of "therapy context" to include those activities that reflected the child's typical day (lunch, recess, soccer, classroom, etc.).

Understanding that every moment is a potential language intervention moment pushed the idea of context in language treatment beyond the previous discrete boundaries. In this view, every interaction offers the child an opportunity to learn about language use and to practice how to be a successful language user. For example, a 10-year-old child on the autism spectrum, M., who the author sees for language intervention, was interested in interacting with a 2-year-old boy, J., who he met each week in the waiting room of the clinic. In his attempt to interact with this toddler, M. often hugged J. a bit too vigorously or spoke to him a bit too loudly. Needless to say, the 2-year-old moved away from M. and backed into his caregiver's lap. In order to help M. express his natural interest in interacting with the young child and to have a more successful experience, the clinician practiced with him how he might approach the boy (i.e., from a distance) and what he might say to him (e.g., show him a toy). In fact, from a pragmatic point of view, the SLP welcomes the opportunity to see how the child functions in different contexts in his or her attempt to make the therapeutic experience representative of the child's typical interactions and to address those missteps that may be interfering with his positive opportunities for interaction.

Finally, in reference to the *role of the adult* during the interaction, pragmatic models of language acquisition and use suggest that the clinician assume more of a partner and less of a teacher role during intervention. The adult is seen as sharing the communicative interaction with the child, not directing it. Often, the idea of "following the child's lead" is used to help parents and professionals understand that the child's ideas and intentions should take precedence over the adult's. With the goals in mind, the adult will support, scaffold, and facilitate development, always

beginning from where the child is and engaging in a dynamic that is more reciprocal and less adult led. The full impact of a developmental-pragmatic approach can be seen as therapy sessions which reflect this thinking, where adults are watching, waiting, observing, and then determining based on the child's actions, behaviors, vocalizations, body movements, and words how the next steps in development can be encouraged.

Efficacy Information

Although many language intervention programs integrate aspects of developmental-pragmatic models of language, two programs in particular reflect the basic tenets of this perspective. The Hanen Program, *More Than Words* (Sussman 1999), focuses on teaching parents to use responsive strategies that promote social interaction and, ultimately, language development. The fact that the training is designed to support the primary caregivers in their interactions with their children places this program at the heart of pragmatic thinking. Recent studies (McConachie et al. 2005; Girolametto et al. 2007) have shown that parents who participated in the *More Than Words* program used more responsive interaction strategies than the control group of parents. Moreover, gains in vocabulary, frequency of communication, and/or participation in turn-taking routines were noted in the children.

Other studies have also investigated the effects of responsiveness training on the caregivers' interactive style and the resulting effects on their child's social interaction and communication. Specific improvements in joint attention, initiation of communication, periods of engagement, and expressive language have been noted in children whose parents became more responsive (Aldred et al. 2004; Baker et al. 2010; Mahoney and Perales 2003, 2005; Siller and Sigman 2002).

The SCERTS (Social Communication, Emotional Regulation, and Transactional Support) program developed by Prizant et al. (2006) represents an educational program which embraces the core components of developmental-pragmatic frameworks. This program emphasizes

functional, developmentally appropriate goals and objectives which are addressed in meaningful and purposeful activities throughout the child's day. The child's individual differences, including learning style and interests, are embraced; the family, educators, and clinicians are seen as a collaborative team.

The description of social communication in the SCERTS program (Prizant et al. 2006) as the "development of spontaneous, functional communication, emotional expression, and secure and trusting relationships with children and adults" speaks to the priorities of all pragmatically oriented programs. Similar to *More Than Words* (Sussman 1999), the fact that the family and professionals are taught to respond to the child's needs and interests is derived from the focus in developmental-pragmatic models on the partner's roles in the child's acquisition of language. Prizant et al. (2010) provide many references to support the positive outcomes of training in social communication, with approaches that range from those that are more behavioral to those that are more representative of developmental-pragmatic ones (Kaiser et al. 2000; Wetherby and Woods 2006).

Outcome Measurement

Measuring progress in pragmatic goals and objectives has always presented its own set of challenges for SLPs. The very nature of pragmatics speaks to the way language use varies relative to changing aspects of the context such as the participants, the setting, nonlinguistic supports, ongoing discourse, etc., making measurement for this area of language more complicated than others. Perhaps, the best way to think about the emergence of pragmatic behavior is relative to a continuum of contexts of the child's life, with outcomes measured within specific contexts (e.g., the child's initiation of communication with one particular peer during toy play). From a pragmatic perspective, intervention progress can only be thought of with an understanding of the dimensions of natural contexts and real-life partners.

The outcome measurements of developmental-pragmatic interventions span a wide range of behaviors. Unlike most other approaches, these include both the child's and the partner's behaviors, as the pragmatic approach is anchored in the caregiver's role in creating interactive exchanges. In fact, the responsiveness of the caregiver to the child's behaviors is seen as one of the most important aspects of interaction to measure. Given the underlying theory of typical language learning, clinicians who are working from this framework will want to track the parent's ability to sensitively respond to all of the child's communicative attempts (not just those that involve spoken language). Parent responsiveness provides more opportunities for social interaction and, ultimately, the acquisition of language.

All of the goals and objectives indicated in the previous section are easily translated into outcomes to measure (occasions of intentional communication, use of a range of speech acts, ability to engage in turn-taking exchanges, etc.). Although behavioral principles could be used to conceptualize how to measure a new behavior (e.g., 80% criterion), a developmentalist may be more comfortable with a continuum of criteria, ranging from "emerging" to "achieved." Developmental thinking implies that measures will mirror how typical development proceeds gradually over time rather than thinking in terms of the use of a particular behavior in 8 out of 10 trials.

Developmental-pragmatic models rely heavily on checklists of targeted behaviors, questionnaires, naturalistic observation, language sampling, and semistructured assessment to measure the child's progress in selected goals and objectives. The frequency of assessment will vary with the program and the system, with some measuring outcomes on a daily or weekly basis, and others over a longer span of time. When outcome measurement is being used to determine the success of a particular step in the program, more frequent assessment leads to more frequent modification of the parameters of the treatment plan. Finally, the SLP who is working from a developmental-pragmatic framework will want to periodically measure the child's

progress across the contexts of his or her life, as a reflection of the ability to use language in the learning and social interactions that make up his or her day.

Qualifications of Treatment Providers

The majority of treatment providers for developmental-pragmatic approaches to language intervention are speech-language pathologists. Those SLPs who are working directly with parents will need additional training in how to teach strategies and procedures for affecting change in the caregivers' interactive styles (e.g., Hanen programs). Other more broadly based developmentally oriented models, such as the Developmental, Individual Difference, Relationship-Based (DIR) approach (Greenspan and Wieder 1998), include training components in their certificate process for professionals from a range of disciplines who want to learn how to "coach" parents effectively. Once SLPs begin working with parents closely, they are often aware of the need for further training in counseling in order to deal with the emotional issues typically and understandably raised by the caregivers.

In addition, SLPs working in this model often collaborate with teachers to help them implement a developmental-pragmatic approach in the classroom. The SLP will be called on to help other professionals shift their thinking to implement the goals and strategies in the contexts of the child's academic and social life. Here, again, the developmental-pragmatic approach requires additional programming and planning on the part of the SLP as the work moves beyond the therapy walls and out into the child's everyday world.

Diagnosis and Classification

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

As used in medicine (including psychiatry), a diagnosis is determined as part of a diagnostic process in the attempt to identify a specific disorder. Diagnoses are used in many ways and for different purposes. As both a term and a process, the issue of diagnosis is very much related to issues of classification. Indeed, the word diagnosis comes through Latin and Greek sources which have to do with understanding/distinguishing things. In clinical medicine, the assignment of a diagnosis often involves various tests, examinations, and so forth; the diagnosis typically guides treatment. In addition, diagnoses have other uses, e.g., in public health, in establishing eligibility for services, and so on. Some special issues arise with

respect to psychiatric diagnosis and are discussed subsequently (see also ► [“DSM-IV”](#) entry).

Historical Background

Although diagnoses have been used since antiquity, it was only as the causes of various medical illness began to be identified in the 1800s that attempts were made to study the issue more systematically, e.g., in relation to causes of death. This effort took place both in Europe and the USA originally focusing on causes of mortality but gradually expanding to include a range of diseases and injuries. This effort results in what is now the *International Classification of Diseases* (ICD-10). In psychiatry, early efforts to assign diagnoses were limited and classification schemes highly theoretical in nature; this limited their use more generally and with clinicians who did not share similar theoretical orientations. This shifted dramatically with the 3rd edition of the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM-III) (American Psychiatric Association 1980) which adopted an atheoretical approach and which quickly came to dominate psychiatric diagnosis throughout the world.

Current Knowledge

Diagnosis is intimately related to issues of classification. The tendency to engage in the latter activity is an intrinsically human activity that has the potential to facilitate observation and then help generate general principles and hypotheses. When approaches to classification are shared, communication is enhanced. In medicine in particular, the assignment of some specific label to a condition may itself be a source of relief to the patient or family members since it is often (mistakenly) assumed that having a label implies an understanding of etiology and specific treatments. As with any human construction, diagnostic labels can be misused. While official systems like DSM-IV or ICD-10 tend to be organized

around categories, other approaches, e.g., using dimensions of function/dysfunction, could also readily be used. Classification systems vary depending on their purpose but to be generally useful that must be amenable to ready and reliable use by a range of individuals. In the past, theoretically based approaches to classification were common but now have given way to more “phenomenologically based” approaches.

A number of misconceptions regarding issues of diagnosis and classification should be noted: (1) by itself, deviant behavior does not need to imply a disorder, and (2) diagnoses do not necessarily have to have a biological base even when symptoms are expressed somatically (e.g., maladaptive personality traits can be a disorder, and severe psychological stress can give rise to a range of persistent physical symptoms).

Issues for classification arise from numerous sources. One has to do with the primary goal(s) of classification (e.g., to enhance research or to facilitate clinical work). Also, there are some special issues for classification in relation to difficulties of childhood onset. The two major classification systems for psychiatric and developmental disorders (DSM-IV and ICD-10) adopt approaches that are in some ways similar and in other ways quite different. Although it is often assumed that some ideal classification system must exist in reality, many different factors impact approaches to diagnosis. To complicate things further, different apparent etiologies might result in rather similar clinical pictures, while sometimes the same etiological factor is associated with a wide range of clinical outcomes; often intervention is much more concerned with the expression of the clinical problem rather than its cause. With a few interesting exceptions (e.g., reactive attachment or post-traumatic stress disorders in DSM-IV), etiologies have typically not been specified.

Difficulties of childhood onset present special problems for classification and diagnosis. Developmental factors must be considered, e.g., in relation to the ways they may impact symptom expression or in the ways the symptoms may interfere with development. The use of a multi-axial approach helps in dealing with this problem. In the past, theoretically based approaches to classification

were common but now have given way to more “phenomenologically based” approaches.

Contextual factors are of great importance in understanding the clinical expression of conditions in children, i.e., family, school, and ethnic or cultural background may significantly impact the clinical presentation. These issues are often most complicated in very young children where disentangling child-maternal difficulties can sometimes be quite difficult. It should also be noted that disorders not individuals are classified (failure to do this results both in problems of stigmatization and potential adverse effects of labeling).

Having one problem may increase risk for other difficulties (what is termed comorbidity). It has been noted that for individuals with intellectual disability, there has often been a tendency to overlook other problems (what is termed “diagnostic overshadowing”). There are different approaches to the problem of comorbidity, and the problem is a special challenge for childhood-onset disorders since having one problem may contribute to risk for another one.

Future Directions

Particularly in the area of psychiatry, DSM-III marked a watershed event in improving diagnostic reliability and significantly advanced research in the field. In autism and related disorders, similar changes have occurred with diagnostic systems becoming more and more data based and, in turn, more likely to advance research in general. New knowledge in the areas of genetics, biological models, and identification of end phenotypes or intermediate endophenotypes may further advance work on these disorders. As noted in detail elsewhere (e.g., Smith et al. 2015), the new DSM-5 definition has resulted in a significant narrowing of the diagnostic concept.

Diagnosis of Autism with Low Mental Age

Lauren E. Miller

Department of Psychological Sciences,
University of Connecticut, Storrs, CT, USA

Definition

Important considerations when diagnosing autism spectrum disorder (ASD) in individuals with low mental age (low MA), defined as verbal and nonverbal functioning below a 12-month developmental level.

Historical Background

ASD can be challenging to diagnose in very young children, as many of the defining characteristics of the disorder (e.g., immature peer relationships, limitations in reciprocal conversational skills, stereotyped interests, or repetitive patterns of behavior) are age- or development-specific. That is, consistent with the timing of social communication milestones in typical development, these skills are not usually seen in infants or toddlers, nor are they apparent in older individuals with low MA (Crais et al. 2006; Ventola et al. 2006; Vig and Jedrysek 1999;

Watson et al. 2003). Comorbid intellectual impairment further complicates the diagnosis of ASD, as certain behaviors observed in children under age 5 years with global developmental delay (GDD), or in older children and adults with intellectual disability (ID), mimic the symptoms commonly associated with ASD (e.g., complex motor mannerisms, immature social skills) (Brereton et al. 2002; Gardner et al. 2018). Current estimates say that the prevalence of co-occurring ID in ASD is approximately 31% (CDC 2018). Individuals with ASD and a comorbid cognitive delay appear to be a particularly severe subgroup, as they tend to make limited developmental gains despite intervention, and they exhibit more significant adaptive, social, and behavioral deficits than peers without intellectual impairment (Gardner et al. 2018; Hinnebusch et al. 2017). Despite the challenge of identifying ASD with co-occurring cognitive and developmental delays, it is possible to diagnose ASD in low MA. Furthermore, it is particularly important to *quickly* (i.e., early in development) and *accurately* diagnose ASD in this very low-functioning population in order to facilitate access to appropriate (i.e., intensive or adapted) intervention services and generate research-informed prognoses for affected families.

Current Knowledge

Although the literature regarding ASD with low MA is somewhat limited, recent research has largely focused on three primary topics that require special consideration in this population: (a) differentiation of ASD and global delays; (b) application of commonly used diagnostic tools; and (c) developmental trajectory, including diagnostic stability.

Whereas individuals with cognitive impairment or GDD are expected to show delays across multiple developmental domains, including verbal abilities, nonverbal reasoning, motor functioning, adaptive behavior, and/or social skills, those with ASD should, by diagnostic definition, exhibit well-defined deficits in communication and socialization, in addition to the presence of

atypical restricted, repetitive behaviors (Osterling et al. 2002; Vig and Jedrysek 1999). As detailed above, however, individuals with low MA often display symptoms of both ASD and GDD or ID. When compared to children with ASD, those with GDD exhibit greater social responsiveness and joint attention (Baranek 1999; Miller et al. 2019; Osterling et al. 2002; Vig and Jedrysek 1999). Recent research on social development suggests that toddlers with GDD, but without ASD, display mild to moderate impairments in more advanced social behaviors, such as pointing (i.e., a key joint attention behavior exhibited by age 1 year in many typical toddlers) and creative and imaginative play (i.e., complex make-believe play that builds on sensorimotor exploration and imitation in the second year of life). Thus, these behaviors are unlikely to be particularly helpful in differentiating ASD from global delays, particularly in youngsters with low MA (Miller et al. 2019). There is some suggestion that delayed children, both those with ASD and GDD, engage in repetitive motor mannerisms in infancy and toddlerhood (Osterling et al. 2002), yet that finding is not universal (Miller et al. 2019). When compared to children with just cognitive delays, those with ASD demonstrate atypical language development, social withdrawal, and immature play, consistent with the defining features of ASD. Regardless of mental age, certain features appear to be indicative of ASD in early childhood, namely, a reduction in the following social behaviors: eye contact, social smiling, facial expressions directed toward others, and responsiveness to one's name (Baranek 1999; Miller et al. 2019; Osterling et al. 2002). It is useful to keep in mind that children with ASD usually show deviations from typical development, particularly in terms of their social communication, yet those with global cognitive deficits are more likely to exhibit delays (Vig and Jedrysek 1999). As such, whereas children with GDD might "catch up" to their typically developing peers, those with ASD may continue on an atypical developmental trajectory, especially if not provided with intensive ASD-specific intervention.

Autism-specific diagnostic instruments directly assess core symptoms of ASD, thereby

helping to clarify diagnosis in cases of complex symptom overlap (e.g., ASD and GDD or ID). However, few “gold-standard” tools are designed for use in individuals with low MA, which serves to further complicate the diagnostic process for low-functioning or very young children. The Autism Diagnostic Interview – Revised (ADI-R), a structured interview for the diagnosis of ASD across the life span, is recommended for use in individuals with a mental age above 2 years. Below the age of 3 years, diagnostic utility is mixed, and the measure reportedly overdiagnoses ASD in cognitively delayed and pre-verbal individuals, regardless of chronological age (Gray et al. 2008; Risi et al. 2006; Ventola et al. 2006). The Autism Diagnostic Observation Schedule (ADOS), which is currently in its second edition, uses play as a means of eliciting social communication behaviors in individuals of all ages, yet it is designed for use in those with a mental age of at least 12 months. Research on application of the ADOS to globally delayed populations is mixed. While in some studies the tool adequately discriminates ASD from other diagnoses, even in significantly delayed toddlers (Ventola et al. 2006), in other studies the ADOS is much less accurate in young and cognitively impaired individuals, particularly children functioning below a 15-month level (Gotham et al. 2007; Risi et al. 2006). In toddlers with low MA specifically, the ADOS uniformly overidentifies a large minority of those with GDD as having ASD (Miller et al. 2019). This overclassification appears to be a product of the relatively complex task demands of the ADOS, which are too challenging for low-functioning children (Gotham et al. 2007). The Childhood Autism Rating Scale (CARS), which is also in its second edition at present, offers another method of ASD diagnosis, namely, a clinician rating scale that takes into account information gleaned from a developmental history, as well as clinical observations of behavior. Although this measure is often aligned with clinical best estimate (Gotham et al. 2007; Risi et al. 2006; Ventola et al. 2006), in children with low MA, the CARS both over (i.e., overdiagnoses)- and under-classifies (i.e., misses) a small portion of significantly delayed

youngsters (Miller et al. 2019). It is thus important for clinicians to exercise some caution in applying and interpreting commonly used ASD diagnostic tools in low MA, as these measures may result in misdiagnosis when used blindly in this population.

Limited research exists regarding the developmental trajectory of individuals with ASD and low MA. That said, they do appear to be a particularly severe subgroup of ASD. Even when identified early (i.e., age 2 years), such children show less developmental growth (i.e., slower progress) in the preschool period when compared to their peers with ASD and higher MA (Hinnebusch et al. 2017). It is important to note that the social deficits observed in individuals with low MA are not merely a product of their cognitive delays. In fact, between the ages of 2 and 4 years, stability of ASD diagnoses in children with ASD and low MA is remarkably high; that is, they remain on the autism spectrum and continue to display significant symptoms, even when provided with early and intensive behavioral intervention (Hinnebusch et al. 2017; Miller et al. 2019). The high stability of symptoms in this vulnerable population provides further support for the legitimacy of diagnosing ASD in the presence of low MA.

Future Directions

With growing attention to the diagnosis of ASD with low MA, there is increased need for adequate diagnostic tools, as well as adapted interventions to best meet the needs of this severe population. When used and interpreted with caution by highly trained clinicians, “gold-standard” ASD-specific instruments such as the ADI-R, ADOS, and CARS may be suitable for the diagnosis of ASD in the context of comorbid low MA. In particular, the new Toddler Module of the ADOS, which is designed for children ages 12–30 months, may be better suited developmentally for young children with low MA. Perhaps the most promising measure for the diagnosis of ASD in young and low-functioning individuals is not yet published for clinical use: Autism Observation Scale for

Infants (AOSI; Bryson et al. 2008). The AOSI is intended for 6- to 18-month-olds and thus should suit most of the low MA population, though it is more of a developmental screener. Further research is necessary to determine the best instruments for the diagnosis of ASD with low MA.

Given the apparent severity and stability of the ASD and low MA phenotype, it is imperative that ASD interventions be tailored to support these individuals. Children who have ASD with low MA make limited developmental progress over time and show greater cognitive, adaptive, and social deficits than their peers with intact cognitive functioning even with intensive intervention (Hinnebusch et al. 2017). This pattern suggests that individuals with low MA may struggle to participate in and respond to traditional ASD-specific intervention services (Gardner et al. 2018). While failure to diagnose ASD in low MA may contribute to even poorer outcomes for this subgroup, current intervention approaches are not sufficient to meet the needs of this population. Thus, investigation of appropriate treatments is strongly indicated, drawing from Applied Behavior Analysis (ABA) and other ASD-specific interventions, in addition to knowledge from special education and neurorehabilitation.

Although there are important and unique considerations related to the diagnosis of ASD with low MA, given what is known about this population thus far, clinicians should have greater confidence in diagnosing ASD regardless of the mental age of the patient at the time of evaluation.

Diagnostic Boundaries of Autism

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

The boundaries of autism – an area where the lines of distinction are increasingly unclear.

Historical Background

In psychiatry the publication of the DSM-III as atheoretical and phenomenological orientation (Spitzer et al. 1978) stimulated considerable

research and helped us ponder boundaries or what was “normal” and “pathological” (often related to issues of distress or impairment.). Boundary issues of normal and psychopathological were particularly complex in the area of personality problems/differences and in the area of developmental disorder like autism. Autism and related conditions, including Asperger’s disorder, provide some of the best models for illustrating the importance of the neurodiversity movement and the recognition of a broader range of the autistic phenotype.

Autism itself was first described clinically in the 1940s but only not recognized as a diagnosis until the 1980s in the landmark DSM-III (APA 1980). There were many problems with this definition (including a lack of developmental orientation), but its official recognition stimulated an explosion of research and helped us better identify and offer treatment to children with ASD with a noteworthy improvement in adult levels of independence and self-sufficiency (Magiati and Howlin 2019).

Current Knowledge

The official recognition of autism also was explicitly noted to mark it out as a condition where there was little dispute that it was so distinctive there were no boundary problems with other conditions, thus providing the best example of a “disorder” in child psychiatry (Rutter and Garmezay 1983).

Subsequent work has shown this not to be the case. Just as we have become aware of the very strong and complex genetics of autism (Yuenn et al. 2019) and differences in the way the “social brain” works in autism (McPartland et al. 2014), we also have become aware of the broader autism phenotype (Ingersoll and Wainer 2014) and the importance of a broader view of what is normal (Allen 2013). The ongoing debate on these issues (Silverman 2015; Greenberg 2013) has been helpful in allowing us to recognize a broader acceptance of the range of patterns of development and behavior.

Future Directions

The concept of neurodiversity has assumed increasing importance in helping us recognize the value and significance of neurological differences and in charting boundaries of the broad range of normal and its border with disorder. This concept has been applied to a range of neurobiological “typologies,” e.g., autism, attention deficit disorder, dyspraxia, and others. It emphasizes the potential value of different ways of cognitive processing and viewing the world. The issue of boundaries of autism and related condition with the broad range of normal development and behavior remains an important area for future work (Ingersoll et al. 2014) as are the potential genetic contributions to these phenotypes (Yuenn et al. 2019).

Diagnostic Evaluation of Language Variation (DELV-Norm Referenced)

Kathleen Hastings, Anna Rogulina and Danielle Asklar
Southern Connecticut State University,
New Haven, CT, USA

Synonyms

[DELV-NR](#)

Description

The Diagnostic Evaluation of Language Variation (DELV) is a group of tests designed to assess speech and language disorders in children who speak a dialect of English other than Mainstream American English (MAE). The DELV was developed by Harry N. Seymour, at the University of Massachusetts Amherst, and Thomas W. Roeper and Jill de Villiers at the University of Massachusetts and Smith College. Their work was completed in conjunction with Harcourt

Assessment, Inc. and support from a National Institutes of Health (NIH) grant (Seymour and Pearson 2004, p. 30). The DELV consists of three separate tests: the DELV-Screening Test (DELV-ST), the DELV-Criterion Referenced Test (DELV-CR), and the DELV-Norm Referenced (DELV-NR) test. The DELV-NR is a diagnostic test that provides a standardized approach to distinguishing between speech and language differences versus delays and/or disorders in children.

The DELV-NR strives toward being a culturally unbiased assessment by differentiating between non-contrastive features of language that are shared between all English dialects and contrastive features that are not. English dialects may express a sentiment using the same rules or linguistic patterns as other dialects resulting in non-contrastive features. Conversely, they may express a sentiment differently, following rules or linguistic patterns which vary from those of other English dialects, resulting in contrastive features (Seymour et al. 2018, pp. 74–76). For example, in MAE the third person form of the linking/copula verb “be” is obligatory in the sentence “She *is* hungry.” However, in African American English (AAE), it is not obligatory to include “is.” Therefore, the linking/copula verb “be” in the present tense would be considered a contrastive feature of English because its usage varies based on the dialect. In comparison, the past tense, third person form of “be” would be required in all major dialects: “She *was* hungry.” This would be considered a non-contrastive feature of English (Seymour et al. 2018, p. 76). By excluding stimuli items that elicit dialectically specific, contrastive elements of language, the DELV-NR focuses in on the more universal, non-contrastive features of English which are used across all dialects of English. Deficits in the use of non-contrastive features of English would be indicative of a true disorder rather than a dialectal difference.

The DELV-NR assesses the language domains of syntax, pragmatics, semantics, and phonology in children regardless of their dialect of English. Each domain is addressed through multiple subtests. The syntax subdomains are as follows: *wh*-questions (10 items), passive sentence

constructions (10 items), and articles (8 items). The subtest items were selected on the basis of representing syntactic features of English that are universal among all of its dialects. The subtests of the second domain, pragmatics, address communicative role taking (4 items), short narrative (1 story, 4 questions), and question asking (9 items). These items measure the child’s overall ability to use social communication and appropriately respond to questions and situations. The semantics domain contains the most subtests: verb contrast (10 items), preposition contrast (6 items), quantifiers (2 subsections, 9 items total), and fast mapping (25 items). These items provide measures of the child’s lexical organization skills. Finally, phonology as a domain assesses consonant clusters produced in the context of a sentence (25 items) (Seymour et al. 2018, pp. 1–2, 14–48).

The DELV-NR is normed for children aged 4 years, 0 months through 9 years, 11 months. It is designed for children who speak English as their first spoken and primary language (Seymour et al. 2018, p. 1). The materials needed to administer the test consist of the examiner’s manual, stimulus book, record form, and a pencil. The assessment takes approximately 45 minutes to administer and 10–15 minutes to score. Scores in syntax, pragmatics, and semantics are reported as domain-scaled scores, test-age equivalents, and percentile ranks. The range of the domain scores is 1–19, with a mean of 10 and one standard deviation of 3. Phonology is reported in percentile band, with 16th percentile representing one standard deviation. Overall language performance is reported as a composite standard score and percentile rank. The composite standard score represents the sum of the domains scores of syntax, pragmatics, and semantics. It has a range of 40–160, with a mean of 100 and one standard deviation of 15 (Seymour et al. 2018, pp. 57–58).

Historical Background

Historically, research has acknowledged that African American and other minority children are disproportionately represented in special

education. Within speech-language pathology, minority children are often overidentified as having a speech or language disorder. The problem of using MAE as the norm against which to compare the speech and language of AAE speakers was publicly raised by Dr. Orlando Taylor at the 1968 American Speech-Language-Hearing Association (ASHA) convention. Debates around issues of diversity, multiculturalism, and dialectical differences at this seminal convention led to the formation of the ASHA Black Caucus (later the National Black Association for Speech-Language and Hearing (NBASLH)) (Moore 2009). Although a growing body of research about the assessment of speakers of non-mainstream English, including AAE, emerged in subsequent decades, no formal assessment instrument was available until the DELV-ST and DELV-CR were published in 2003. In 2005, DELV-NR became the first standardized assessment tool aimed specifically at assessing children who speak AAE and other variations of English. Based on a 2014 study, the DELV-NR resulted in diagnostic sensitivity and specificity of 0.85 and 0.93, respectively, data that supports the diagnostic validity of the DELV-NR (Pearson et al. 2014, pp. 503–505). In 2018, Ventris Learning reprinted the DELV-NR and the DELV-ST, having made minor updates but no substantial changes to either test (R. Meyer, October 11, 2019, publisher, personal communication).

Psychometric Data

The stimuli items selected for the domains of the DELV-NR were derived from an initial battery of 350 items. A group of 1370 test-takers from across the USA, including 450 speakers of MAE, 800 speakers of AAE, and 120 individuals who spoke other dialects, participated in refining the assessment material. This initial test group included children with language impairments, who together represented nearly 30% of the sample (Bland-Stewart and Pearson 2006). To create an appropriate dialect-neutral set of

questions, specific criteria were required for the final group of items which were included on the DELV-NR. Collectively, items needed to both differentiate between typically developing children and impaired children and discriminate between expected development in the age bands between the ages of 4 and 9 (Bland-Stewart and Pearson 2006). At the same time, items needed to be non-contrastive, resulting in minimal differences regardless of the dialect of English spoken by the test-takers. Researchers analyzed the children's responses to each test item until they determined a set of items which satisfied these criteria (Bland-Stewart and Pearson 2006).

A sample of over 900 participants was used in the standardization of the DELV-NR edition. Data from the 2002 US Census Current Population Survey of children aged 4–9 years was utilized to represent the demographic characteristics within the US population. The authors based their standardization sample on this data in an attempt to closely mirror the percentiles across demographic categories (Seymour et al. 2018, p. 109). The following classifications were examined within the demographic analysis of the sample: age, sex, race/ethnicity, parental education level, and region. Sex, race, and ethnicity (African American, Asian, Hispanic, other, and White), region (North Central, Northeast, South, and West), and parent years of education were categorized. Multiple analyses were completed within each age bracket to further compare sample norms to the equivalent distribution within the general US population. A comparison of race/ethnicity revealed 16.44% of the sample was African American (compared to 15.66% of the US population), 4.89% of the sample was Asian (compared to 4.68% of the US population), 14.00% of the sample was Hispanic (compared to 14.19% of the US population), 1.34% of the sample identified as other (compared to 1.23% of the US population), and lastly 63.33% of the sample was White (as compared to 64.24% of the US population) (Seymour et al. 2018, p. 111). Analysis of dialectic differences within the sample revealed that 80.8% of participants

spoke MAE. Of the remaining participants, 8.0% spoke AAE, another 7.7% of participants spoke Southern American English, and the final 3.5% spoke other dialects (Seymour et al. 2018, p. 110).

The age of sample participants ranged from 4 years (4:0) to 9 years and 11 months (9:11). There was a total of nine age intervals within the standardization sample, including age bands of 4:0–4:5, 4:6–4:11, 5:0–5:5, 5:6–5:11, 6:0–6:5, 6:6–6:11, 7:0–7:11, 8:0–8:11, and 9:0–9:11. Each subsection was represented by 100 children (Seymour et al. 2018, p. 109). Within the standardization sample, there was also a subset of children with clinical speech and language impairments. This population was represented within 6.8% of the sample by children who had been diagnosed with a receptive and expressive language disorder. Additionally, 4.2% of the sample was identified as having an articulation/phonological disorder, 2% were identified as developmentally delayed, and 1.7% was recognized as gifted. No children within the standardization sample were diagnosed with a fluency or voice disorder. Close to 9% of the sample received some type of special education service, a figure which included speech and language services. Some children demonstrated both speech and language disorders (Seymour et al. 2018, p. 110). Data from a study by the National Institute on Deafness and Other Communication Disorders was used to determine the percent of children with language disorders, which determined the prevalence of specific language impairment within the general population of kindergarteners in the USA to be 7.4%. This statistic was used to determine what percentage of the standardized sample should be represented by children with language disorders (Seymour et al. 2018, p. 110).

Reliability was examined using measures of test-retest, internal consistency, and interscorer reliability. The test-retest reliability score was based on data collected from 239 children from the original standardization sample who were given the test twice 6–28 days apart, administered

by the same individual in most cases. The stability coefficient for the individual domains of syntax, pragmatics, semantics, and phonology (for all ages combined) ranged from 0.78 to 0.91. The composite standard score test-retest reliability (for all ages combined) reached a score of 0.90 (Seymour et al. 2018, p. 121).

Internal consistency was measured using two methods and across two population samples: general and clinical. Based on the coefficient alpha technique, the internal consistency reliability coefficient for individual domains ranged from 0.75 (adequate) to 0.93 (excellent) and reached 0.88 for the composite standard score based on data from the general population (Seymour et al. 2018, pp. 122–123). Internal consistency of the individual domains and the test as a whole was even higher when the test-takers were children with a language or articulation disorder. Based on this clinical sample of 118 children, the internal consistency reliability coefficient for individual domains ranged from 0.82 to 0.93 and reached 0.93 for the composite standard score (Seymour et al. 2018, p. 124). The split-half method confirmed that internal consistency was slightly higher for the clinical sample than the general population, both at the level of individual domains and the overall composite score. The average internal consistency reliability coefficient (split-half) was 0.91 based on the general population and 0.94 based on the clinical sample (Seymour et al. 2018, pp. 123–124).

A value for the standard error of measurement (SEM) was also derived to calculate confidence intervals. The average SEM ranged from 0.91 to 1.42 scale-scored units depending on the domain. The average SEM of the composite standard score was 4.69 scale-scored units (Seymour et al. 2018, pp. 125–126). Finally, the average interscorer reliability of the DELV-NR was very high, ranging from 0.93 to 1.00 depending on the domain (Seymour et al. 2018, p. 125).

Some evidence of validity for the DELV-NR is based off information gleaned from correlation studies which looked at subtests of the *Clinical Evaluation of Language Fundamentals*, Fourth

Edition (CELF-4) and *Preschool Language Scale*, Fourth Edition (PLS-4) Articulation Screener. In one validity study, 61 children from the standardization sample of the DELV-NR were also assessed on the CELF-4. Despite some differences in testing format, low to moderate correlations were found between the CELF-4 and various domains of the DELV-NR edition, including a 0.35 correlation between the Expressive Vocabulary subtest of the CELF-4 and the semantics domain of the DELV-NR; a 0.38 correlation was found between the Understanding Spoken Paragraphs subtest of the CELF-4 and the syntax domain of the DELV-NR; and a 0.40 correlation was found between the Sentence Structure subtest of the CELF-4 and the syntax domain of the DELV-NR, as well as a 0.29–0.39 correlation between the Word Classes subtest of the CELF-4 and the semantics domain of the DELV-NR. These results appear to confirm the test developers' expectation that only a low to moderate correlation would exist between the DELV-NR and the CELF-4 because the two tests do not share the same underlying theoretical principles (Seymour et al. 2018, pp. 131–132). As expected, a higher correlation was found between the DELV-NR and the PLS-4 Articulation Screener based on a validity study of 1,104 children, 116 of whom had been diagnosed with articulation disorders. The correlation between PLS-4 screener and the phonology domain of the DELV-NR was 0.87. Together, these scores suggest that the DELV-NR edition has evidence of validity as an assessment tool for language and articulation disorders (Seymour et al. 2018, pp. 133–135).

Another measure which provides salient evidence for the validity of the DELV-NR is the diagnostic validity statistics. These statistics suggest that at one standard deviation (1 SD) below the mean, the DELV-NR has excellent sensitivity and specificity, with sensitivity equaling 0.95 and specificity equaling 0.93 (Seymour et al. 2018, pp. 140–142). One recent study has probed the assessment tool at 1.5 SD below the mean and also found the accuracy of the DELV-NR to be excellent, with a sensitivity of 0.85 and a specificity

of 0.93 when assessing a population of students with a 30% language impairment prevalence (Pearson et al. 2014, pp. 503–505; Seymour et al. 2018, p. 141). The premise of that study was that language sample (LS) measures, such as those analyzed by the Systematic Analysis of Language Transcripts (SALT) protocol, would provide a more accurate reference against which to compare the diagnostic value of the DELV-NR. Results showed that the “accuracy of the DELV-NR relative to LS profiles was greater than that of prior diagnoses, indicating that the DELV-NR was an improvement over preexisting diagnoses for this group” (Pearson et al. 2014, p. 495).

In regard to content validity, the DELV-NR edition includes stimuli items with non-contrastive features shared between speakers of MAE and AAE, a measure which is sensitive to language disorder rather than language difference. It uses this model to assess across the modalities, including semantics, syntax, phonology, and pragmatics (Seymour et al. 2018, p. 127).

Furthermore, evidence based on response processes included a thorough examination of children's incorrect responses to explore the plausibility of other possible answers for each question. This process included an examination of the reasoning behind a child's response and resulted in some changes for assessment questions as deemed appropriate and necessary (Seymour et al. 2018, p. 128).

Additionally, the validity of internal structure was assessed to understand how intercorrelation between the domains may impact testing on the DELV-NR edition. Low to moderate correlations were found which may reflect interconnectivity of language domains in language tasks (Seymour et al. 2018, pp. 128–129).

Clinical Uses

Research supports the usefulness of the DELV-NR as an assessment tool for diagnosing a language disorder. The DELV-NR analyzes scores on multiple domains of language and is shown to have excellent sensitivity (0.95) and specificity

(0.93) to diagnose a language disorder at one standard deviation below the mean as the cutoff score (Seymour et al. 2018, pp. 140–142). Based on the composite standard score, the test was shown to have excellent test-retest reliability, good to excellent internal consistency, and very high interscorer reliability (Seymour et al. 2018).

The usefulness of the DELV-NR as an assessment of articulation is more limited. The DELV-NR appears to have only “good” sensitivity (0.85) and “adequate” specificity (0.75) to diagnose a phonological/articulation disorder at one standard deviation below the mean as the cutoff score. The overall sensitivity is fair compared to other well-known and frequently used assessments (Seymour et al. 2018, pp. 140–142). As stated in the Examiner’s Manual, “The Phonology Domain by itself is not designed to provide in-depth information about the nature of a child’s phonological/articulation disorder. If a child’s percentile band score is below or includes the 16th percentile, you should evaluate the child further to determine the exact nature and scope of the child’s problem” (Seymour et al. 2018, p. 65). Differentiating between a phonological and an articulation disorder would also require the use of additional diagnostic tools.

The DELV-NR is based on robust standardization research, which included 900 children between the ages of 4;0 and 9;11 and was designed to reflect population demographics as reported in 2002 US Census Current Population Survey (Seymour et al. 2018, p. 109). Because the DELV-NR is normed on the general US population, its diagnostic value extends to both speakers of MAE and speakers of nonmainstream English, including AAE (Pearson et al. 2014). However, its greatest strength is in filling the gap in existing standardized language assessments by providing a dialect-neutral testing battery for culturally and dialectically diverse populations.

Children’s dialectal differences may be overidentified as language disorders, requiring students to receive speech and language services, while actual disorders may be under identified. The DELV-NR responds to the need for a systematic means of distinguishing between a language

difference and a disorder. A recent, independent study has concluded that the DELV-NR provides better diagnostic accuracy than prior tests for this population, when using the Systematic Analysis of Language Transcripts (SALT) protocol results as the benchmark. Specifically, the sensitivity and specificity values of the DELV-NR were found to be 0.85 and 0.93, leading the authors to conclude that “even after making allowances for the imperfection of available gold standards, clinical decisions made with the DELV-NR achieved high values on conventional measures of diagnostic accuracy” (Pearson et al. 2014, p. 495).

Diagnostic Instruments in Autistic Spectrum Disorders

Christina Corsello

Department of Psychiatry, Child and Adolescent Services Research Center, University of San Diego, San Diego, CA, USA

Definition

Diagnostic measures are designed to capture behaviors in the areas of communication, reciprocal social interactions, and restricted and repetitive behaviors that characterize an autism spectrum disorder. These measures attempt to quantify behaviors associated with an autism spectrum disorder by assigning them numerical scores. These quantitative behavior scores are then translated into summary scores that result in a classification that is typically either consistent with one of the autism spectrum disorders or not. Current diagnostic instruments include parent questionnaires and interviews as well as standardized observational measures. The time and training required to administer and score these instruments varies from minimal for parent questionnaires to more involved for observational measures and semistructured interviews.

Historical Background

One of the first widely used scales for identifying children with autism was *The Rimland Diagnostic Form for Behavior Disturbed Children* (Form E-1; Rimland 1968). This measure was an important development in the field, as it focused on identifying carefully selected symptoms of autism. Another early diagnostic measure developed at around the same time was the *Behavior Rating Scale for Autistic and Atypical Children* (BRIAC; Rutter et al. 1966). This measure is historically significant because it was the first to be based on actual observations of behavior from clinician case notes rather than parent report.

The *Handicaps, Behaviors and Skills Schedule* (HBS; Wing and Gould 1978) was also an early influential measure because it was the first widely used semistructured parent interview and it contributed to the understanding of the “triad of impairments” that has led to our current understanding of autism. Not technically considered a diagnostic measure, the HBS was a framework for gathering information regarding symptoms and behavior that could be utilized in a clinical evaluation. This measure has been revised and is currently known as the *Diagnostic Interview for Social and Communication Disorders* (DISCO; Wing et al. 2002 – see below).

Another scale of importance in the initial group of diagnostic measures was the *Behavior Autism Rating Scale* (BOS; Freeman et al. 1978). This measure was the first instrument that emphasized controlling the environment in which the child was observed, as well as standardizing the behaviors that were observed (Lord and Corsello 2005).

Most of these measures have been revised, with Rimland’s Form E-1 becoming Form E-2, the HBS now the DISCO, and the BOS leading to the development of the Real Life Rating Scale (RLRS; Freeman et al. 1986).

Diagnostic measures have evolved over time, both because diagnostic criteria have changed with each revision of the Diagnostic and Statistical Manual, Fourth Edition (DSM-IV), and because empirical studies continue to provide information about how well each measure differentiates children with autism from those without autism based on current definitions. The diagnostic measures have changed as we have learned more about the disorder, including the expansion of age range and developmental levels of children included within this diagnostic group.

As the current gold standard in autism diagnostic measures, the *Autism Diagnostic Observation Schedule* (ADOS; Lord et al. 2000) illustrates the change from DSM III to DSM IV criteria to now include Asperger’s syndrome and pervasive developmental disorder, not otherwise specified on the spectrum. This measure evolved from its original form developed in the 1980s to its current form which includes five modules for assessing toddlers through adults with module choice

dependent on the individual's age and language level. The *Childhood Autism Rating Scale* (CARS; Schloper et al. 2010) is another example of this evolution, with the addition of a scale for high-functioning autism, as the original version missed many children with better language and cognitive skills.

Current Knowledge

There are currently several measures available for diagnostic purposes, ranging from those that are very quick to administer and require minimal training to those that take more time and training. As with any other psychometric measure, diagnostic measures are evaluated based on reliability and validity data. This section will cover the most widely used and available diagnostic protocols. For more detailed information on these measures, please see the respective individual entries included within this encyclopedia (Table 1).

Parent Questionnaires

The Autism Behavior Checklist (ABC): This questionnaire is one component of the *Autism Screening Instrument for Education Planning* (ASIEP; Krug et al. 1980), now in its third revision. It builds on several other measures, including Rimland's Form E-2, the BOS, and the BRIAAC. It contains five items across five areas, and ranges are provided to distinguish a high probability of autism, a low probability of autism, or mixed probability. Standard scores are available for children between the ages of 3 and 13 years. It was initially intended to be completed by teachers or other professionals working with a child. This measure requires no special training. It has also been used with parents on a retrospective basis for children with high-functioning autism. One concern regarding this measure, however, is its low sensitivity, as many children on the spectrum appear to be missed using the suggested cutoff score.

The Australian Scale for Asperger's Syndrome (ASAS): This questionnaire includes 19 items covering five areas and is scored on a seven point Likert-type scale. It is designed to be completed

by a teacher or parent and covers ages 3–19 years. The authors recommend that the measure be used as a screener rather than a diagnostic measure because of low specificity. There are little published data available on this measure, and the original study had several methodological issues, including raters who were not blind to diagnosis. Though the measure does not result in a classification of Asperger's disorder, as a screener, it provides information on whether a child should receive a diagnostic evaluation.

Behavior Summarized Evaluation – Revised (BSE-R): This rating form is comprised of items from two overlapping instruments, the *Behavioral Summarized Evaluation Scale* (BSE) and the *Infant Behavioral Summarized Evaluation Scale* (IBSE; Barthelemy et al. 1997). It is primarily designed to document behavioral symptoms associated with autism as they relate to neurophysiological measures. These scales consist of 20 items scored on a five-point Likert scale by trained raters on the basis of direct or videotaped observation, discussion of the child's history, and access to information from multiple sources. It covers the ages of 18 months through 12 years and takes approximately five minutes to administer. Interrater reliability and convergent validity is reported to be strong.

The Childhood Autism Rating Scale – Second Edition (CARS-2): This rating form has been one of the strongest, best documented, and most widely used rating scales for behaviors associated with autism. It consists of 15 items on which children and adults are rated, generally after observation, on a four-point Likert scale and results in classifications of not autistic or mild to severe autism. This measure, most commonly completed by a clinician based on observation, requires minimal training and approximately 15 min to complete. The revision of this measure includes a form to better capture children with high-functioning autism and is recommended for use with individuals whose IQs are above 70 and who are over the age of 6 years. The original CARS form has not changed and is included in the CARS-2 for use with children under the age of 6 years or who have lower IQ scores. The CARS-2 was recently adapted, and there are not

Diagnostic Instruments in Autistic Spectrum Disorders, Table 1 Summary of measures

Measure	Format	Administration time	Age range	Diagnostic criteria used	Training	Suggested use
SRS	Parent/teacher/self-report questionnaire	15 min	Preschool to adulthood	DSM-IV	None	Screening/ response to treatment
SCQ	Parent/caregiver questionnaire	15 min	Preschool to adulthood	DSM-IV	None	Screening
GARS-2	Parent/caregiver questionnaire	15 min	Preschool to adulthood	DSM-IV	None	Screening
CARS-2	Clinician rating based on observation	30 min	Preschool to adulthood	DSM-III-R	Minimal	Diagnostic
BSE-R	Rating based on observation, review of records, and interview	5 min	1½ to 12 years	N/A	Yes	Symptoms for research
ABC	Teacher questionnaire	Not specified	3–13 years	DSM-IV	Minimal	Measure maladaptive behavior
PDDRS	Parent questionnaire	Not specified	Not specified	DSM-III-R	None	Screening
GADS	Parent questionnaire	10 min	3–22 years	DSM-IV	Yes	Assess Asperger's disorder behavior
ASAS	Parent or teacher questionnaire	10 min	3–19 years	Not specified	None	Screening
ADI-R	Semistructured interview	1.5–3 h	Toddler to adulthood	DSM-IV	Yes	Research and clinical diagnosis
DISCO	Semistructured interview	2–3 h	Any age	ICD-10	Yes	Assess individual needs, treatment goals
ASDI	Semistructured interview	Not specified	Not specified	Gillberg's criteria	None	Screening
AOSI	Semistructured observation	20 min	6–18 months	DSM-IV	Yes	Early identification
ADOS	Observation	30–60 min	Toddler to adulthood	DSM-IV	Yes	Research and clinical diagnosis
PEP-III	Caregiver report and clinical observation	45–90 min	1–7 years	DSM-IV	Minimal	Assess development, create treatment goals

yet many research studies evaluating the effectiveness of the rating scale for children with high-functioning autism.

The Gilliam Asperger's Disorder Scale (GADS): This parent questionnaire consists of 32 items and is based on DSM-IV and ICD-10 criteria of Asperger's disorder. It takes

approximately 5–10 min to score and also includes a parent interview section that is not scored but provides information on language and cognitive and adaptive behavior which is important in differentiating Asperger's disorder from other autism spectrum diagnoses. Like the Gilliam Autism Rating Scale (GARS), this measure

results in an Asperger's quotient of low or high probability of an Asperger's disorder. As with the GARS, the standardization sample diagnosis was reported by parent or professional and not confirmed.

The Gilliam Autism Rating Scale – Second Edition (GARS-2): This questionnaire has recently been revised and is now known as the GARS-2. It consists of 56 items across four subscales, covers the ages between 3 and 22 years, and takes approximately 5–10 min to administer. The measure is based on DSM-IV and Autism Society of America criteria and results in an autism quotient that indicates whether a child has a “low probability” or a “high probability” of having autism. No training is required. The measure is intended for screening; however, several studies using the original version of the GARS found that it missed up to 52% of the children who met diagnostic criteria for autism clinically and received scores within the autism range on other standardized diagnostic measures (South et al. 2002). The initial normative sample was large, but the diagnoses were reported by the parent and not confirmed. Revisions to the GARS-2 have attempted to address these concerns by lowering the cutoff score and providing a new normative sample. As with the initial normative sample, not much information is available on the group. While the measure is considered to be appropriate for use with adults, scores should be interpreted cautiously because only 9% of normative sample was over 16 years (Montgomery et al. 2008).

The Pervasive Developmental Disorders Rating Scale (PDDRS): This measure is a revision of an earlier scale (Eaves 2003). It includes 51 items across three subscales and is based on the DSM-III-R. Each behavior is based on a five-point Likert scale. A child is considered to fall within the range of an autism spectrum disorder if both the total score and arousal score fall one standard deviation below the mean. No standard diagnostic procedure was used to define the sample, and therefore the suggested use of the PDDRS is for screening only.

Social Communication Questionnaire (SCQ): This questionnaire, formerly known as the *Autism*

Screening Questionnaire, is based on a well-validated standardized parent interview, the *Autism Diagnostic Interview – Revised (ADI-R)*. It was initially designed as a screening measure and consists of 40 items that cover the areas of communication, reciprocal social interactions, and restricted and repetitive behaviors and interests. It is designed to be filled out by a parent and takes approximately 15 min to complete. No training is required, and scoring instructions are available in the manual.

There are two versions of the measure, a “current” version that is designed for children under the age of 5 years and covers current behavior, and a “lifetime” version that is designed for children over 5 years of age to adulthood and covers early behavior, focusing on the ages between 4 and 5 years. For children under the age of 5 years, several studies have found that a lower cut off score of greater than or equal to 12 results in the greatest diagnostic differentiation. For those older than 5 years of age, scores of greater than or equal to 15 are considered to be significant and suggestive of a possible autism spectrum disorder.

Little information is available on its use with children under the age of 3 years. It works fairly well as a screener for children over the age of 3 years, with the modified cutoff for children under the age of 5 years. It has higher specificity than many screening measures, and its performance has been found to be similar to a standardized diagnostic interview in at least one study (Corsello et al. 2007).

Social Responsiveness Scale (SRS): This questionnaire was initially developed to measure social and communication difficulties along a continuum. It consists of 65 items covering the areas of communication, reciprocal social interactions, and restricted and repetitive behaviors and interests. Gender norms are available, and the measure results in a T-score and a social severity impairment score ranging from typical to severe. Both a teacher version and a caregiver version are currently available, and each takes approximately 15–20 min to complete. The SRS does not require training to administer, and instructions for scoring are included in the manual. The first version of the SRS was designed for children between 4 and

18 years of age. More recently, two additional versions have been developed and are available for research use and are soon to be available for use clinically: an adult version in a self-report and other report form, and a preschool version. Suggested uses include screening and response to treatment.

Semistructured Interviews

The Autism Diagnostic Interview – Revised (ADI-R): The ADI-R is one of the most widely validated diagnostic measures available. Based on DSM-IV criteria, it is administered as a semistructured interview by a clinician to a parent or caregiver, and covers current behavior for all children and historical information for older children and adults. The measure consists of 89 items that are coded on a 0–3 point scale, several of which are transferred to a diagnostic algorithm that results in a diagnostic classification. One of the biggest weaknesses of this measure is administration time, which is between 1.5 and 3 h. The extensive reliability and validity data available for the ADI and the clinically rich information it provides make this measure the gold standard in research despite its lengthy administration time.

The Asperger's Syndrome (and High-Functioning Autism) Diagnostic Interview (ASDI): This measure was designed as a diagnostic tool for verbally fluent individuals with autism and Asperger's disorder. It is a semistructured interview based on Gillberg's criteria and includes 20 items that operationalize six criteria. The interviewer is instructed to obtain descriptions of actual behaviors to accurately code each item. This interview does well in distinguishing Asperger's disorder from psychiatric disorders and normality, but has yet to develop a means of distinguishing Asperger's from autism (Gillberg et al. 2001).

The Diagnostic Interview for Social and Communication Behaviors (DISCO): This measure is a standardized semistructured interview based on the HBS, and it is now in its ninth revision. It was designed to obtain behaviors relevant to the diagnosis of autism for the purpose of assessing individual needs and development across several areas. The DISCO includes items that cover the areas associated with autism spectrum disorders,

as well as developmental items and atypical behaviors. This measure was not originally designed for diagnostic purposes, but rather to assist clinicians in generating recommendations for older individuals with an autism spectrum disorder. Diagnostic algorithms have been developed for research purposes.

Observational Measures

The Autism Diagnostic Observation Schedule (ADOS): The ADOS is one of the most widely studied and used diagnostic instruments, and, along with the ADI-R, is considered the gold standard in research studies. It is a semistructured observational measure that consists of several tasks that are administered to a child or adult for diagnostic purposes. The measure includes a number of coded behaviors that allow for assessment in the areas of communication, reciprocal social interactions, and restricted and repetitive behaviors and interests. Scores are transferred to an algorithm and result in a classification of autism, autism spectrum disorder, or non-spectrum.

The ADOS is based on DSM-IV criteria and takes approximately 30–60 min to administer. It is organized into five modules covering children of toddler age who use little or no phrase speech to older children and adults with fluent language. A toddler module has recently been added. Now there are also revised algorithms designed to improve specificity without sacrificing sensitivity, as well as newly developed severity scores for the purpose of measuring change over time. The ADOS requires training and experience with autism spectrum disorders.

The Autism Observation Scale of Infancy (AOSI): The AOSI is a semistructured, standardized observational measure designed for infants between 6 and 18 months of age. It consists of 18 items covering specific behaviors that have been considered to be early indicators of a later autism spectrum disorder diagnosis based on empirical studies and clinical experience. Training on administration and scoring is required. Interrater reliability on a small sample of infants was good to excellent with the exception of a subset of items at the 6 month assessment. Interrater reliability scores on a small sample

were fair to good. Reliability was calculated using kappas, and a skewed distribution may affect results. Scores at the ages of 12 and 18 months were considered to be predictive of a later diagnosis of autism. Available data has been on high-risk infant groups, primarily high-risk siblings, and on relatively small samples. The intended use of this measure is to identify children who may be likely to later meet criteria for a diagnosis of autism in a high-risk sample, and it is available for use in research protocols (Bryson et al. 2008).

The Psychoeducational Profile Revised (PEP-3): This measure was designed to assess development and diagnostic characteristics of children with an autism spectrum disorder. This measure was designed for children between 12 months and 7 years of age. The PEP-3 consists of a pathology section that is designed to measure the severity of behaviors associated with autism spectrum disorders. There is little information available on the reliability or validity of the pathology section. The PEP-R was primarily designed to assess development and create treatment goals. This measure requires approximately 45–90 min to administer and requires experience with children with autism spectrum disorders. The suggested uses are primarily to create treatment goals and to assess development.

Future Directions

Diagnostic measures continue to be modified and refined as more is learned about their effectiveness, as the diagnostic criteria for autism spectrum disorders changes with new revisions of the diagnostic manual, and as health-care funding changes. There continues to be a need for measures that can be used for research and clinical purposes. Standardized observational measures are generally brief enough to be used as part of a clinical evaluation or research protocol. Several studies suggest that using both a standardized parent interview in conjunction with a standardized diagnostic observational measure and clinical judgment results in the most accurate diagnosis. However, the most well-validated diagnostic interview, the ADI-R, is long and takes time to

administer. As funding changes, there is an increasing need for more efficient diagnostic measures, and consequently, attempts have been made to use more questionnaires and to decrease the length of time required to conduct standardized interviews. Screening measures and questionnaires are also being refined to make them more suitable for diagnostic use in research protocols.

As a field, we have begun to recognize younger children as at risk for autism spectrum disorders, requiring measures that can identify toddlers that may later develop the disorder. Interviews and questionnaires are also being extended, downward to identify the youngest children and upward to better capture older and higher functioning children with autism spectrum disorders. As treatment attempts to address the core deficits of autism spectrum disorders, there have also been requests to develop measures that can capture response to treatment. This has, in part, led to the development of severity scores for the ADOS.

The fifth revision of the DSM is expected within the next few years and will lead to modifications in current measures to match the new diagnostic criteria. Currently there are several very strong diagnostic measures available for use for screening or diagnosis of autism spectrum disorders. The diagnostic measures in the field of autism are dynamic and evolving, with their widespread use in both clinical and research settings leading to modifications for practical application and improved effectiveness.

DISCO

Description

The Diagnostic Interview for Social and Communication Disorders (DISCO) (Leekam et al. 2002; Wing et al. 2002) is a semi-structured interview schedule used with the parent or carer of an individual to elicit a broad picture of the individual's behaviors and needs. Its primary purpose is to elicit information relevant to the autistic spectrum in order to assist clinicians in their judgment of an individual's level of development, disabilities, and specific needs. It contains sets of algorithms for diagnosis of autism according to the international classification criteria (ICD and DSM) and other sets of diagnostic criteria. Key features of the DISCO are (a) that it can be used for children and adults of any age, (b) that it collects extensive information not only on the core symptoms of autism but also beyond these symptoms (e.g., sensory symptoms, emotion symptoms, gross and fine motor skills, psychiatric and forensic problems, maladaptive behavior, sleep difficulties), and (c) that it has a strong developmental focus, including the detailed assessment of current developmental level and developmental delay.

The Diagnostic Interview for Social and Communication Disorders (DISCO) is based on a concept of a spectrum of autistic disorders that predated the earliest ICD and DSM criteria for

autism and pervasive developmental disorders (Wing 1988, 1996; Wing and Gould 1979). This concept is similar to, but wider than, the concept of pervasive developmental disorders (PDD) described in DSM-IV and ICD-10. Therefore, the use of the DISCO enables diagnosis of specific autism conditions according to DSM-IV, DSM-5, and ICD-10, but the DISCO goes beyond this. Information collected is placed in a broad developmental and behavioral context that reflects a dimensional view of a spectrum of autistic disorder and emphasizes its broad-ranging nature. An individual's difficulties with reciprocal social interaction, communication, and repetitive behavior can therefore be understood against the pattern of their developmental skills and associated abilities and difficulties. In addition, symptoms of other related disorders (e.g., language, attention, or motor impairments) can be elicited for further investigation. Furthermore, as the DISCO is concerned with the assessment of needs as well as with the diagnosis of ASD, the information it collects is relevant for guiding recommendations relating to management and interventions.

The DISCO interview schedule comprises more than 300 questions that are organized into eight parts. Part 1 provides a factual record of family, medical, and identifying information. Part 2 deals with the first 2 years of life. This infancy section consists of medical questions relevant to the diagnostic criteria for Rett's syndrome and a further set of questions relating to behaviors. Part 3 "Developmental Skills" forms the largest part of the DISCO. This section comprises subsections related to the following domains: (a) gross motor skills, (b) self-care, (c) domestic skills, (d) independence, (e) verbal and nonverbal communication, (f) social interaction with adults and peers, (g) social play and leisure, (h) imagination, (i) pictures, reading, and writing, (j) visuo-manual skills, and (k) cognitive skills. All the items are rated by the interviewer in terms of three aspects: (a) current level, (b) delay in acquiring relevant skills, and (c) atypical (or unusual) behavior associated with the relevant skills. The atypical behaviors cover both the past and present behaviors.

Other parts of the DISCO also record both the past and present behavior patterns of the individual. Part 4 on repetitive activities includes subsections on stereotypies, atypical sensory responses, and repetitive routines. Part 5 on emotions includes questions on anxiety and mood changes. Part 6 on maladaptive behavior is concerned with behavior that impinges adversely on other people such as aggression and temper tantrums and disturbances of sleep. Part 8 on psychiatric conditions and forensic problems includes considerations of a range of psychiatric conditions relevant for adolescents and adults that may need further investigations such as symptoms of schizophrenia, personality disorders, and eating disorders, and this part also includes specific subsections on catatonic features and sexual problems.

Finally, there is a separate section (Part 7) to help guide clinicians to arrive at a clinical judgment independent of quantitative results. This part includes the interviewer's judgment on the quality of social interaction, social communication, social imagination, and overall pattern of activities. Whereas elsewhere during the interview, the aim is for the interviewer to establish the facts related to specific skills or behavior, in Part 7, the ratings are made on an overview of all the available information. This part of the schedule usually does not involve direct questioning of the informant and elicits judgments by the interviewer.

As mentioned above, the DISCO enables diagnosis of specific autism conditions according to DSM-IV category "pervasive developmental disorders" (American Psychiatric Association [APA] 1994), DSM-5 category "autism spectrum disorder" (American Psychiatric Association [APA] 2013), and the ICD-10 category "pervasive developmental disorders" (World Health Organization [WHO] 1993). Selected items throughout the interview provide the diagnostic criteria not only for these diagnostic systems but also for other diagnostic systems. Other diagnostic systems include (a) Kanner's early infantile autism (Kanner and Eisenberg 1956), (b) Asperger's syndrome based on Gillberg and Gillberg (1989) (Ehlers and Gillberg 1993; Wing 1981), (c) autistic spectrum disorder (Wing and Gould

1979), and (d) Wing and Gould's definition of social impairment.

Completion of the entire interview takes approximately 2–3 h, and this provides a comprehensive picture of the individual's skills and abilities. This is particularly useful for complex cases. However, it is possible to adapt the DISCO for specific purposes. For example, where the clinician needs only to obtain information on the current clinical picture, questions about delays in development and past behavior can be omitted. It is also possible to complete the interview using only items relevant for the diagnostic algorithms. DSM-5 item sets for a new DISCO-Abbreviated interview have been published (Carrington et al. 2014, 2019).

The DISCO is distinctively different from other interview schedules, such as the Autism Diagnostic Interview-Revised (ADI-R) (Lord et al. 1994), that were designed to be closely related to the ICD-10 research criteria for childhood autism (WHO 1993) and for DSM-IV autistic disorder (APA 1994). The DISCO is more detailed in the information it collects and is broader and more developmental in focus. For example, the interviewer collects information on a very large number of separate items each covering specific examples of types of behavior, from the most common to the rare, in order to facilitate the final clinical judgments. The interviewer also records the individual's current developmental level and their developmental delays for all domains of functioning. Finally, the interviewer can then apply a number of algorithms for different diagnostic systems using the DISCO.

A number of research studies have been published (see also section “[Psychometric Data](#)” below). Research using the DISCO includes examination of its algorithms for, ICD-10 childhood autism (Leekam et al. 2002; Nygren et al. 2009; Maljaars et al. 2012) and for ICD-10 Asperger's syndrome (Leekam et al. 2000). Algorithms have also been published for DSM-5 (Kent et al. 2013), for DSM-5 Abbreviated (Carrington et al. 2014), and for Wing and Gould's autistic spectrum disorder (Leekam et al. 2002). Research using the other algorithms – DSM-III-R pervasive

developmental disorders (American Psychiatric Association 1987), Kanner's and Eisenberg's criteria (Kanner and Eisenberg 1956), and Wing and Gould's definition of social impairment – has not yet been published.

Research using the DISCO has also led to new knowledge about the role of developmental, behavioral, genetic, and neuropsychiatric factors in the autism profile. Research studies have documented ASD symptoms and behavioral profiles in Rett's syndrome (Wulffaert et al. 2009a), Cornelia de Lange syndrome (Wulffaert et al. 2009), mild intellectual disability (Soenen et al. 2009), gender dysphoria (de Vries et al. 2010), fetal alcohol syndrome (Mukherjee et al. 2011), and the link between epilepsy and autism symptoms (Danielsson et al. 2005; Turk et al. 2008). The DISCO has also been used in several epidemiological studies (Ellefsen et al. 2007; Brugha et al. 2011). Research using the DISCO has also given insights into the nature of catatonia in the autism spectrum (Wing and Shah 2000), the nature of pathological demand avoidance within the autism spectrum (O'Nions et al. 2016), adult outcomes of autism (Billstedt et al. 2007; Cederlund et al. 2008), and pattern and frequency of sensory symptoms in those with ASD (Leekam et al. 2007a).

In addition, to research using the DISCO as an interview, items within the DISCO have been extracted to form research questionnaires and checklists for research purposes. Early checklist studies used items later to be included in the DISCO and these examined empirical clustering of symptoms and cognitive abilities (Prior et al. 1998) and the relation between language delay and diagnosis (Eisenmajer et al. 1998). More recently new questionnaires have been created from DISCO interview items. The Repetitive Behaviour Questionnaire-2 for children (Leekam et al. 2007) and Repetitive Behaviour Questionnaire-2A for adults (Barrett et al. 2015) have been used to examine the relationship between repetitive behavior and other factors including imagination, language, sensory symptoms, and anxiety (Honey et al. 2007; Barrett 2018; Lidstone et al. 2014) in both children and

adults with autism. The RBQ2-A has also been used in longitudinal studies of typically developing children to examine different subtypes of repetitive behaviors predict specific developmental outcomes as children get older (Larkin et al. 2017; Uljarević et al. 2017).

Training for the DISCO has been developed by Dr. Judith Gould and Dr. Lorna Wing and consists of a 4-day training course in two stages. Training covers the Lorna Wing Centre's method of diagnosis, the complexities of diagnosis and assessment of needs, and the specialist psychological assessment. Stage 1 is for 2 days preceded by pre-course work and followed by evaluated interim coursework. Stage 2 is for 2 days leading to accreditation. A computer program is available for accredited users. Training is available for clinicians involved in diagnosis and assessment of needs and for professionals who use DISCO for research. Information about training is available from the following email address: lornawing-centre@nas.org.uk.

Historical Background

The origins of the DISCO are to be found in a study comparing children with autism with children with other disabilities (Down's syndrome, developmental receptive language disorders, developmental expressive language disorders, partial sight, and partial hearing) and a group of children with typical development (Wing 1969). The "Childhood Behavior Schedule," a questionnaire sent to parents by post, was designed for this study. It elicited information concerning the social, language, imagination, and motor impairments and the odd responses to sensory input and stereotyped behavior found in autism. These behaviors are now covered in much more detail in the DISCO.

The original questionnaire schedule was reorganized and expanded to include items on developmental skills and was named the "Handicaps, Behavior, and Skills (HBS)" schedule. A variety of sources were used when constructing the developmental items, including Cooper et al.

(1978), Egan et al. (1969), Griffiths (1967) and Sheridan (1973, 1977). The HBS was used for research in an epidemiological study of autism spectrum disorders in children in the former London Borough of Camberwell (Wing and Gould 1979) and in a follow-up of the children into adult life (Wing 1988). The original epidemiological study was designed to identify children with any of the features of autism in order to see if any clinical patterns could be discovered. This distinguished it from previous studies (e.g., Lotter 1966, 1967) which looked specifically for children showing the narrow criteria originally suggested by Kanner and Eisenberg (1956).

The DISCO interview schedule was developed from the HBS schedules for use in diagnostic work for both clinical work and research purposes. It was designed to include referrals with associated physical or psychiatric conditions or other developmental disorders such as dyslexia and dyspraxia. The schedule was developed to be relevant for all these variations in the clinical pictures. It has been expanded to include past behavior from infancy onward as well as for current state. It is also suitable for use with adults (see section on "Clinical Uses" below).

Reliability and validity studies of the DISCO items were published in 2002 (see section on "Psychometric Data" below), when the ninth version was current (Leekam et al. 2002; Wing et al. 2002). The schedule has had two subsequent minor revisions and the current version is the 11th revision, and research has been published on both these versions (see "Psychometric Data" section).

Psychometric Data

The psychometric properties of the DISCO have been examined in studies carried out in the UK, in Sweden, the Netherlands, and Belgium. The UK studies (Leekam et al. 2002; Wing et al. 2002) used DISCO-9 to carry out inter-rater reliability and validity analyses with data from 82 cases aged 3–11 years. Thirty-six had autistic spectrum disorder, 17 had learning disability, and 14 had

language impairments. Inter-rater reliability was analyzed for over 400 items in the interview. Inter-rater reliability was high with kappa coefficient or intra-class correlation at .75 or higher for over 80% of the interview items. Analyses with the same sample examined two algorithms based on the ninth revision of the schedule (DISCO 9). Algorithm diagnoses were applied to interview items in order to analyze the relationship between clinical and algorithm diagnoses and the inter-rater reliability between interviewers for each algorithm output. Results showed that clinical diagnosis was significantly related to the diagnostic outputs for both algorithms and inter-rater reliability was high for both algorithms. The ICD childhood disorder algorithm produced more discrepant diagnoses than the Wing and Gould's autistic spectrum algorithm. Analysis of the ICD-10 algorithm items and combination of items helped to explain the reason for these discrepancies.

The Swedish study (Nygren et al. 2009) used a translation of the tenth version of the DISCO (DISCO-10). Validity analysis compared DISCO-10 algorithm diagnoses with clinical diagnoses and with Autism Diagnostic Interview-Revised (ADI-R) algorithm diagnoses in 57 cases of children and adults. Results showed good to excellent inter-rater reliability in 40 cases. The criterion validity was excellent when compared with clinical diagnoses and the ADI-R. The report concluded that although the DISCO-10 is not as widely used as the ADI-R, the evidence shows that it has the same level of psychometric credibility.

Psychometric research was carried out by Maljaars et al. (2012) using the Dutch translation of the DISCO-11. Their study included young children with different levels of intellectual disability (ID) including no ID, borderline, mild, moderate, and severe ID. DISCO algorithms for ICD-10 childhood autism and atypical autism were used in comparison with clinical classification and the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 1999) and Social Communication Questionnaire (SCQ; Rutter et al. 2003) to examine its criterion and convergent validity. Sensitivity and specificity of the DISCO

were .96 and .79, respectively. Strong agreement was found between DISCO-11 and ADOS classification ($k = 0.69$, $p < 0.001$), although lower agreement was found with the SCQ ($k = 0.49$, $p < 0.001$). Comparisons with clinical diagnosis showed correct classification for the majority of cases with mismatches mainly explained by cases in the moderate and severe ID range. These results confirm that the DISCO has good criterion and convergent validity. This was especially the case for those with average intelligence or mild intellectual disability. However, the specificity was lower for those with moderate and severe levels of intellectual disability ($IQ < 50$), in line with previous findings.

The most recent psychometric study (Kent et al. 2013), used DISCO data to test the DSM-5 Draft description. The study used different ways of combining the rules for a DSM-5 diagnosis. It also tested the DSM-5 criteria on children and adults with different ability levels. Using the optimal rules for diagnosis described in the study (the Modified algorithm), sensitivity and specificity of the DISCO were 1.0 and 0.84, respectively. In a follow-up study, highly discriminating, "essential" items were identified from the DSM-5 algorithm, to try and identify a reduced set of items that could guide diagnosis. Abbreviation of the DSM-5 algorithm did not significantly affect either sensitivity or specificity within the research samples tested (Carrington et al. 2014). Moreover, a subset of items from the abbreviated DSM-5 item that best discriminated between individuals with autism and individuals with non-autism clinical diagnoses were identified. This set of just 14 items had excellent predictive validity according to best estimate clinical diagnosis, and also showed excellent agreement with established DSM-5 and ICD-10 DISCO algorithms (Carrington et al. 2015).

Clinical Uses

The DISCO schedule can be used in clinical practice to fulfill three main purposes – to provide a clinical description, to make a clinical diagnosis, and to provide recommendations.

First, it can be used to provide a *clinical description* by assisting the clinician in collecting information needed to compile a developmental history and a description of the present clinical picture. This information, including current level of development in everyday skills and the pattern of behavior, can be used as the basis of a narrative clinical report. Usually, the informant is someone who has known the person concerned from birth. However, when the DISCO is used with an adult and no informant is available to give an early history, the items of the DISCO schedule can be completed for current skills, deficits, and atypical behavior. Second, the DISCO can be used to assist in making a *clinical diagnosis* of autism spectrum disorders as well as of other disorders of development affecting social interaction and communication. Related to this purpose, the schedule can be used to run a number of different diagnostic algorithms according to different classification systems (see “[Description](#)” section earlier). In the case of an adult, where no developmental history is available, a diagnosis according to DSM and ICD is not possible, but the information gathered from the DISCO allows the experienced clinician to use their clinical judgment to make a working diagnosis in order to plan a management program. Finally, another important purpose of the DISCO is to provide information that will guide a clinician’s recommendations concerning programs of education, adult support, and management of behavior.

Diagnostic Interviews

Ann S. Le-Couteur and Thomas P. Berney
Institute of Health and Society, Sir James Spence
Institute, Newcastle University, Royal Victoria
Infirmary, Newcastle upon Tyne, UK

Definition

The diagnostic interview (DI) is a central component of the process (diagnostic process) in which, for a variety of reasons ranging from research to the development of an intervention plan, a decision is made as to whether there is sufficient evidence in an individual's symptoms and signs for a diagnosis of one or more of the "disorder(s)" defined by the criteria of the internationally agreed diagnostic classification systems (► [DSM-5](#)).

Historical Background

Following the initial descriptions of autism and Asperger syndrome in the 1940s, agreed criteria emerged slowly and a number of checklists were developed which matched a list of symptomatology against the criteria evolving at the time in ICD 9 (1975) and DSM-II (1980) (DSM-III) focusing on accounts of observable behavior, particularly in childhood, notably the E-2 (Rimland diagnostic form for behavior disturbed children (E-2)) and the Autism Behavior Checklist (ABC).

In the 1960s, in both America and the UK, the search for greater consistency and precision in psychiatric diagnosis led to the development of standardized diagnostic interviews; initially schedules of standard questions, these became elaborated into a more clinical interview that encouraged the interviewer to cross-examine the patient until the nature of the symptom was clear (Wing et al. 1967). A decade later, the same model led to the development of more systematic interviews in making the diagnosis of autism (as the prototypical disorder of the pervasive developmental disorders). Wing and Gould produced the

Handicaps, Behavior, and Skills Schedule (HBSS) which they later refined into the Diagnostic Interview for Social and Communication Disorder (DISCO), Schopler and Reichler developed the Childhood Autism Rating Scale (CARS), and Le Couteur, Rutter, and Lord produced the Autism Diagnostic Interview (later revised to become the ADI-R) (Autism Diagnostic Interview-Revised). These standardized diagnostic instruments consist of a semi-structured interview (based on the agreed symptom criteria) with an adult informant and became recognized as the “gold standard” in terms of their comprehensiveness and reliability in obtaining a clinical history.

The identification of a broader spectrum of autism disorders (ASD), going beyond the original narrow definition for autism, led to an extension of the content and form of ► [diagnostic instruments](#) in autistic spectrum disorders. Examples of these are the Asperger Syndrome Diagnostic Interview (ASDI) and the Autism Questionnaire (AQ) (Baron-Cohen et al. 2001) for Asperger syndrome, the Pervasive Developmental Disorder in Mental Retardation Scale (PDD-MRS) for people with intellectual disability (Kraijer and de Bildt 2005), and the Diagnostic Interview Guide for use in general adult psychiatry (Royal College of Psychiatrists 2011). The recognition of autistic traits (broader autism phenotype – broader spectrum prevalence) in the relatives of people with ASD has led to the development of a variety of interviews to identify these behavioral and personality characteristics.

In many of these, the emphasis was on obtaining material from informants (usually parents) about behavior. At the end of the 1990s, the Autism Diagnostic Observation Schedule (ADOS) was developed as a play and activities based assessment with the individual; this assessment is described as a series of tightly defined, detailed observations which systematically elicits autistic symptomatology.

In the last decade, the number of instruments, their use varying from screening to diagnosis, has reflected the mounting interest in ASD, while increased public awareness and the Internet have fostered the growth of self-rating scales and the demand for confirmatory diagnostic interviews.

Current Knowledge

The Content of the Interview

There are a variety of models for conducting a diagnostic interview. The structure or framework for the DI is important, but there is no compelling evidence to recommend any particular interview format for any specific situation. For all DIs (irrespective of the interview format), the underlying context is the social engagement and interaction between the interviewer and the interviewee. The interviewing skills and attitudes of the interviewer (clinician or researcher) affect the quality of the interaction which in turn influences the success of the information-gathering process. The responses of the interviewee (also affected by many factors including whether they already know the interviewer; the interviewee is in fact the subject of the interview; his or her intellectual and communicative ability, motivation, emotional state, and so on) and the setting can also influence the outcome and “success” of the diagnostic interview (DI).

It should include:

1. An account of the individual’s current concerns – the symptoms that have brought to interview at this particular time and their development.
2. A systematic survey of the symptomatology associated with ASD, especially that which is directly related to the diagnostic criteria. This review should also include consideration of other behavioral features known to be commonly associated with ASD such as motor coordination, sensory and perceptual symptoms, and feeding and bowel problems. It should include any other behavioral problems recognizing that these can occur in response to a variety of potentially modifiable influences from toothache to a change in school timetable or work colleagues.
3. The wider setting – the individual’s everyday life and activities, relationships, and accomplishments.
4. The structure of their family and any history of developmental or psychiatric disorder.

5. An account of the individual's development and their acquisition of skills, not just in infancy and early childhood but subsequently, through school and after, to give a detailed "developmental history".
6. An account of any other anomaly, past or present, including developmental, psychiatric, or medical disorder as well as of any other adversity including deprivation or substance abuse.

The DI will usually be complimented by a direct examination of the individual together with the collation of background reports (including direct observation in other settings). All these sources of information will contribute to the accuracy and value of the final, "best estimate," diagnostic conclusions which, in turn, will inform the multiagency needs- and skills-based management plan.

While the DI and examination are conceptually distinct, in practice, there is likely to be a substantial overlap. For example, when an individual is being interviewed and asked to provide their own account, the clinician will be considering the way the account is being given, the quality and content of the social interaction, and other individual characteristics (such as their appearance, behavior, and communication). These factors will inevitably affect the interaction between the clinician and the interviewee, thus shaping the course of the DI.

How the DI progresses is at least in part dependent on the skills of the interviewer, their training and expertise, as well as the setting of the interview and the expectations of the interviewees. All these different aspects can foster a "dialogue" between clinician and individual. Instruments may be combined for history-taking and observation although, in the end, the distinction between them is one of emphasis rather than clear-cut. For example, while the framework of observational ratings is central to the ADOS, it is also a semi-structured interview.

The Format of the Diagnostic Interview

The interview may take a range of formats depending on its purpose:

1. *Unstructured.* The structure is not immediately apparent, but the interviewer's impression determines the content, purpose, and conclusions of the interview. Its primary purpose may be a different one with diagnosis as a secondary consideration. Such an assessment depends greatly on the individual clinician's experience, and for this reason it is likely to be difficult to understand or replicate.
2. *Semi-structured/interviewer based.* The interview, usually based on a predetermined diagnostic framework, has well-defined symptoms to be explored. Usually conducted in a conversational style, it takes the form of required questions supplemented by additional, optional, open-ended prompts as necessary until there is sufficient information for the trained interviewer to make the coding judgment for each item and section of the interview. The precision and clarity with which symptoms and their codings are defined contribute to the quality of the instrument.
3. *Structured/respondent based.* The trained interviewer closely follows a defined format without deviation; the interview may be restricted further by giving the interviewee a limited number of choices. The interviewer is not called upon to make any clinical judgment (and, indeed, may not know very much about ASD and other diagnoses to complete the interview).

The result is a relatively high inter-rater reliability and an interview that lends itself to being turned into a self-completion questionnaire. This can be administered as a pre-interview contribution or completed in a computerized format (e.g., the E-2 or Autism Spectrum Quotient (AQ) questionnaires). Increasingly for some individuals, access to this type of questionnaire has been a staging post in their journey to diagnosis.

4. *A composite.* The interview incorporates the material from a preinterview questionnaire. Not only is this a more effective use of time, substantially shortening the DI, but many individuals are more comfortable (and therefore more open) with the impersonality of a self-

completion questionnaire. Examples of DIs that use information-collected preinterview include the Developmental, Dimensional, and Diagnostic Interview (3Di) (Skuse et al. 2004) and the Adult Asperger Assessment (AAA) (Baron-Cohen et al. 2005).

It is difficult to define the point at which the self-completion or screening checklist becomes a more formal diagnostic instrument as this will depend on the skill, experience, and intent of those employing it.

The more standardized the format for gathering and organizing the information, the greater the consistency in the data collected and the diagnoses arrived at by clinicians and researchers of varied experience and views and from different centers. However, validity is lost with increasing rigidity that limits the clinician's skills. Using agreed diagnostic systems permits prospective research as well as making clinical material available for retrospective review for service and academic analysis. The whole process is more transparent and can be taught to trainees.

The style of interview has to be appropriate to the task in hand: a structured interview, with its very narrow, specific remit, will be used for screening or surveys and as such can be administered by a technician. The semi-structured interview provides the framework for a more in-depth assessment when a definitive research or clinical diagnosis is required and usually includes one or more summary algorithms to identify ASD using prespecified thresholds. However, the protean presentations of ASD and the demands of clinical work mean that, in the end, even the best of these instruments does not remove the need for knowledge and experience of ASD in coming to a clinical diagnosis which will inform the diagnostic formulation and intervention planning. There are cases, notably in adulthood, of individuals with less clear-cut presentations where it is difficult to discern the pattern of symptoms. It is here that the experience of working with a wide variety of people across the variations of age, ability, gender, ethnicity, and comorbidity makes it possible to appreciate the characteristic impairments of

ASD. In addition, within the assessment team, there needs to be sufficient knowledge and experience to recognize the developmental and psychiatric disorders that are associated with ASD (notably attention deficit hyperactivity disorder (ADHD) (► [Attention Deficit/Hyperactivity Disorder](#)) and developmental coordination disorder (► [Developmental Coordination Disorder](#))).

The choice to use a particular diagnostic instrument will be informed by both the purpose of the interview and the features of the instrument. For example, the ADI-R (► [Autism Diagnostic Interview-Revised](#)) provides a summary lifetime diagnosis, using information about early childhood and the current state for key aspects of behavior and development and a record of the particular unusual behaviors (such as restricted, repetitive mannerisms and stereotyped behaviors) relevant to the decision as to whether probably all references to Pervasive developmental disorder should now be replaced with autism spectrum disorder is present or not. The frequency and intensity of each symptom is carefully graded to give a detailed quantified picture of key components. The DISCO (► [Diagnostic Interview for Social and Communication Disorders](#)) takes a rather broader approach to arrive at a systematic description that allows the identification of other developmental disorders. The 3Di is a computer-based interview designed to focus on current functioning to assess autistic traits, social impairments, and comorbidities in children of normal ability. The content of the interview generates a structured report with summary algorithms of symptom profiles for autism and common non-autistic comorbidities. By contrast, the CARS (► [Childhood Autism Rating Scale](#)) draws on observation as well as interview. The format is much less structured, guiding the interviewer through the relevant domains rather than individual symptoms, requiring the researcher/clinician to reach the coding decisions through the integration of information from subject and informants

Most structured instruments (► [Diagnostic Instruments in Autistic Spectrum Disorders](#)) have been designed for a specific group, often

defined by age (e.g., childhood) or ability. This means that the phrasing or materials might not be suitable for a different “client” group when adaptation of materials and further reliability and validity studies would be required.

As adults come forward for diagnosis, including, for example, those with a severe intellectual disability, women of normal ability, and individuals with preexisting psychiatric and personality disorder diagnoses, the challenge will be how best to tailor the format and content of the DI appropriately. A particular issue is the necessity of a developmental history to confirm that the evidence of delayed or deviant development dates back to early childhood. This becomes particularly important in adulthood should there be a need to differentiate ASD from other disorders (such as schizophrenia (► [Schizophrenia](#)) or dissocial or obsessive-compulsive personality disorders (► [Obsessive-Compulsive Disorder \(OCD\)](#))). However, it is this client group who may experience real difficulty finding an informant with accurate knowledge about their early development.

Whatever the format of the DI, training in its use is required. This applies especially to standardized instruments where the more structured the interview, the more straightforward the training. While it may be obtained by attending a specific training course, receiving in-house individual tuition, or using a self-taught program, it should include a check that clinician/researcher has reached an acceptable standard of accuracy and reliability. This should be followed by regular opportunities to maintain consistency and reliability over time. Undertaking the rating of standardized videos or attending joint sessions with colleagues can help to maintain best practice in administration of the procedure as well as reliability between colleagues and different centers. However, because this is time consuming and may be seen as additional pressure on scarce resources, it is all too easily overlooked.

Implementing the Interview

A DI may take place as a single event in one setting or be spread across several sessions and settings. The venue (clinic, specialist center,

home, school, or other setting) will depend on the needs of individual, their family/carers, clinicians, and services. For example, a very anxious individual or a disabled relative may only be accessible in the home; a clinic may be the only place to get the opinion of a busy clinician or be the best place to provide the structured, calm setting needed to see someone at their best. It may be necessary to go to a school, nursery, or workplace to see the context and thereby understand what is happening there. Observation in different settings may allow some distinction to be made between what behavior is pervasive and what is situational and in response to a particular environment or set of circumstances.

The DI must provide sufficient information for the interviewer to decide whether the symptoms and signs are:

1. *Sufficiently pronounced in their intensity or frequency* to cross the threshold that separates so-called normal variation for developmental progress and personal characteristics from disorder: threshold that may well vary according to the problems experienced by the individual, the context and situation, and the “demands” and expectations placed upon them. For example, a young child who has managed well in their home with a supportive family may find it much more difficult to settle into an educational setting such as preschool if they do not have sufficiently flexible communication, social and play skills to join in with other young children or cope with new and unexpected changes in routine in an otherwise familiar environment. Similarly, an adult who may have learnt to manage effectively in a particular workplace may still find that he/she is less able to succeed in social and more personal relationships. For the diagnostic interview to be successful, the interviewer needs to understand the importance of gathering information about the development of the individual’s behavior in different settings and contexts over time. This may well require (especially for children and young people but often also for adults) information from other

informants who know the subject well in different settings.

2. *Sufficiently close to the currently agreed criteria* (► **DSM-5**) for a diagnosis of ASD or might be explained better by some other disorder. ASD is a neurodevelopmental disorder defined by its onset in early childhood, something that may be difficult to confirm in later adulthood.

The interview therefore has to enable the clinician to distinguish the signals of ASD against the background noise of other, complicating disorders, particularly other developmental and psychiatric disorders such as intellectual disability, specific speech and language disorders, attention deficit hyperactivity disorder (ADHD), epilepsy, and/or mental health problems such as anxiety or obsessive-compulsive disorder.

The interview must also be appropriate *to its immediate purpose*: for example, the requirements for inclusion in a research study might be more stringent than those needed as the basis for clinical or administrative planning.

A diagnosis may be sought for many reasons, ranging from inclusion in a research study, accessing specific treatments and interventions, eligibility for particular education provision, achieving financial benefits, and gaining family understanding, through to assisting a court to understand the needs of the individual. Most importantly, it can give the individual a more complete understanding of their profile of strengths and impairments. The diagnostic interview also provides a benchmark against which subsequent progress can be measured. It has to be tuned accordingly to meet these specific requirements.

The results of the interview should be valid (i.e., that others would agree with the diagnostic conclusions) and reliable (they would be the same if repeated, whether by the same clinician or others). The process needs to be acceptable to all, sufficiently transparent to be understood, and sufficiently valued for the results to be useful.

Most instruments require the interviewer to make judgments and ascribe a numerical score to each item in the assessment. These scores may be

collated to give symptom and/or domain scores which can be summarized within one or more instrument-specific diagnostic algorithms. For a number of instruments, usually those that have been developed for research, the reliability and validity of the algorithm scores and instrument-specific diagnostic thresholds have been tested and refined in different populations. However, it is important to recognize that a diagnostic algorithm score derived from a particular instrument may contribute to, but is not equivalent to, a clinical diagnosis. This is something broader, using an internationally agreed diagnostic classification system, based on information gathered from several sources, and often involving professionals working in different agencies to provide a multidisciplinary assessment. This information, in turn, will contribute to, but is not sufficient for, the development of a management plan. The DI, which may include the use of a structured instrument, is an opportunity for the development of a dialogue between the interviewer, the individual, and the family/carer and, as such, can also provide the context for sharing the outcome of the multi-agency assessment.

One of the great values of using an agreed diagnostic classification system is that it facilitates the possibility of successful research collaborations between clinical academic centers as well as making clinical material available for service review and analysis. With greater transparency between services and centers, there is an increase in research capacity, the ability to share new knowledge and significant developments, and in opportunities for trainees to learn from the experiences of their colleagues.

Future Directions

A number of standardized instruments are now in routine use for the DI providing both a valuable framework for the history as well as the basis for the start of a therapeutic relationship with individuals and families. Many are time consuming and resource intense, and this has to be balanced against the benefits of the therapeutic alliance and detailed descriptions of behavior. While the use of a detailed

DI may well be appropriate for a behavioral syndrome that has such a variety of presentations and underlying disorders, there is great pressure to develop briefer processes and ever greater consistency while maintaining validity.

The value of increasingly sophisticated online questionnaires as an adjunct to the DI needs to be investigated. New measures will also be required as further understanding of the complexity of the autism spectrum across the lifespan becomes available. However, the development of new instruments is a complex and expensive task. An equally important challenge is to investigate the best ways of getting reliable information from different sources to complement the DI this will enable the clinician/researcher, referred individual, and family to achieve a valid diagnostic formulation that in turn leads to an accurate needs- and skills-based management plan.

The recognition of autistic traits in the families of people with autism has led to the development of instruments to identify these which, once sufficiently validated and standardized, will be published.

In spite of many claims and much research, there is still no reliable laboratory test for ASD. However, even if such a test were ever developed, its results would complement the diagnostic interview rather than replace it, a model seen in other medical conditions as, for example, the use of genetic testing in the clinical diagnosis of Down or Rett syndrome.

With increasing awareness and understanding of ASD, there is likely to be greater emphasis on the identification of the strengths, skills, needs, and impairments of the individual and their family, as well as on diagnosis, to inform a dimensional diagnosis and profile across different domains of functioning. Although separate assessments may be needed to measure different aspects of an individual's functioning (e.g., social responsiveness, language and flexibility, anomalies in sensory sensitivity and motor coordination), this information will always need to be collated alongside the findings of a DI to achieve a diagnostic formulation. At least for the foreseeable future, classification systems used in clinical and research practice, together with other social

and resource pressures, will continue to require a categorical diagnosis of ASD.

Diagnostic Overshadowing

Steve Kanne

Department of Health Psychology, School of Health Professions Thompson Center for Autism and Neurodevelopmental Disorders, University of Missouri, Columbia, MO, USA

Definition

Diagnostic overshadowing refers to the negative bias impacting a clinician's judgment regarding co-occurring disorders in individuals who have intellectual disabilities or other mental illness. Symptoms or behaviors that may be due to a specific mental illness are attributed to another disorder, historically Mental Retardation, without considering alternative etiology.

Historical Background

Reiss, Levitan, and Szyszko first coined the term "diagnostic overshadowing" to describe the tendency to assess individuals with intellectual disability less accurately (Reiss et al. 1982a, b; Reiss and Szyszko 1983). Subsequent research has consistently demonstrated that the cognitive deficits displayed by an individual negatively impacted the ability of clinicians to make accurate judgments with regard to other co-occurring disorders (c.f., Jopp and Keys 2001; White et al. 1995).

Jopp and Keys provide a review of the concept of diagnostic overshadowing in addition to possible moderators (Jopp and Keys 2001). Their

review indicated that most clinician-based variables, such as nature of clinical position (e.g., school, clinical and counseling psychologists, social workers), educational level (e.g., graduate student vs. Ph.D.), and years of experience, were not associated with the strength of the bias. Moreover, though the presence of multiple disabilities would presumably be more inherently difficult to disentangle for a diagnosing clinician, the research clearly indicated that the clinician's perception of the cognitive deficits present in the individual being assessed was the most salient feature reducing diagnostic accuracy.

Diagnostic overshadowing causes clinicians to overlook a range of comorbid mental illness in individuals with intellectual disability, including phobias, schizophrenia, avoidant personality disorder, and depression (Jopp and Keys 2001). As Jopp and Keys note, the bias potentially serves to reduce both sensitivity and specificity – two important components of accurate diagnosis. Sensitivity refers to the ability to accurately diagnose individuals who have a disorder, while specificity refers to the ability to accurately rule out individuals who do not have a particular disorder. Diagnostic overshadowing may reduce sensitivity by creating more false negatives, such as when a child with a cognitive deficit is not diagnosed with an anxiety disorder that they truly have. It may also reduce specificity by increasing the number of false positives, such as when a child is diagnosed with an intellectual disability, when they really have another disorder that has caused the cognitive deficit.

Only one factor has been found to moderate the impact of diagnostic overshadowing, which is how clinicians process information, termed cognitive complexity (Jopp and Keys 2001). That is, when a clinician is able to view a patient's behaviors in a multidimensional fashion, incorporating a wide range of thoughts, feelings, and behaviors, which in turn leads to generating multiple hypotheses, the impact of the patient's cognitive deficits and the resulting diagnostic overshadowing can be reduced.

The concept of diagnostic overshadowing has direct epidemiological implications. If diagnostic accuracy is impacted and individuals are missed

with regard to a diagnosis, or misdiagnosed, then prevalence data may be misleading or incorrect. Moreover, epidemiological studies not only inform prevalence and incidence of a disorder and its associated characteristics, but can also help guide etiological understanding. For example, this was especially the case in autism wherein the initial report of the prevalence of co-occurring epilepsy in autism led to scientists to examine biological mechanisms in contrast to the non-biological theories promulgated at the time (Bryson and Smith 1998; Lotter 1974). If diagnostic overshadowing causes clinicians to overlook important co-occurring disorders, advancements in etiological understanding may also be impacted.

Current Knowledge

More recently, clinicians and researchers have extended the notion of diagnostic overshadowing beyond individuals with cognitive deficits to those with other disorders such as autism. In addition, diagnostic overshadowing has been extended beyond the diagnostic process to discussions regarding how it may impact treatment. For example, some researchers have found that diagnostic overshadowing has direct treatment implications. How an individual is diagnosed affects what treatments are recommended by their treating providers. If the treating provider is affected by diagnostic overshadowing and thus does not recognize other disorders, those other difficulties will not be appropriately treated. Minnes and Steiner found that parents of children with Down syndrome, for example, reported more problems receiving treatment for the co-occurring illnesses, such as cataracts, thyroid problems, and possible dementia (Minnes and Steiner 2009).

Researchers have proposed that the same mechanism biasing clinicians who work with individuals with cognitive deficits may also apply to clinicians who work with individuals with autism. More specifically, given the wide range of cognitive abilities in addition to the other symptoms of autism, such as

communication problems and other challenging behaviors, clinicians may be underdiagnosing comorbid disorders in individuals with autism, despite the accumulation of evidence that demonstrates a high prevalence of co-occurring disorders in autism such as mood disorders, attentional disorders, and behavioral disorders (Simonoff et al. 2008).

Others have demonstrated how diagnostic overshadowing has impacted epidemiological research results. For example, Charman and colleagues, using the Special Needs and Autism Project sample (i.e., total population cohort of 56,946 children in the UK ages 9–10), compared the concordance of their research-based diagnosis to the diagnoses derived from local services in children with IQs above and below 70. They found that the amount of children diagnosed with an autism spectrum disorder from local services who had cognitive impairment was less than those in that group that had been diagnosed through their epidemiological research design, 25% compared to 45% (Charman et al. 2009). These results demonstrate the potential diagnostic overshadowing bias and its impact on prevalence rates of autism depending on method of ascertainment.

Future Directions

In their 2001 review, Jopp and Keys noted four areas in need of research with regard to diagnostic overshadowing which remain relevant despite the broadening of diagnostic overshadowing beyond intellectual disability: (1) improve specification of clinical decisions that make up diagnostic overshadowing, (2) note the processes whereby diagnostic overshadowing occurs, (3) increase the appreciation of other variables such as the environment as they impact overshadowing, and (4) explore overshadowing more fully using qualitative and other methodologies (Jopp and Keys 2001). How much overshadowing actually takes place in local and “real world” clinics, as opposed to the vignettes used in the research that explore its presence, needs to be more fully explored, as well as a better delineation of how diagnostic

overshadowing is impacting other diagnoses, such as autism, in addition to cognitive deficits alone.

Diagnostic Process

Johnny L. Matson and Julie Worley
Department of Psychology, Louisiana State
University, Baton Rouge, LA, USA

Definition

Autism spectrum disorders (ASDs) are a group of heterogeneous disorders that share overlapping diagnostic criteria. These include deficits in communication and socialization, and restricted interests and repetitive behaviors. Deficits in socialization are the hallmark of all ASDs, and deficits in this area are diagnostically required to meet criteria for all of the ASDs. Important to note is that even with these three core domains of impairment, heterogeneity across these symptoms exists on an individual basis. As such, the classification systems used to categorize the core impairments in ASD have been amended over time. Even still, the diagnostic process of ASD is complicated by numerous factors including the differential diagnosis within ASDs, a push to identify symptoms of ASD at very young ages, and the stability of ASD diagnoses over time. Thus, this entry will review these factors in regard to the diagnostic process of ASD.

Historical Background

Autism spectrum disorders were first introduced into the diagnostic nomenclature in 1980 (i.e., *Diagnostic and Statistical Manual of Mental Disorders, Third Edition [DSM-III]*; American Psychiatric Association [APA] 1980) under the category of pervasive developmental disorders. However, two of the currently recognized diagnoses, pervasive developmental disorder not otherwise specified and Asperger's disorder, were not introduced as diagnostic disorders until 1987 and 1994, respectively. Although the diagnostic categories have changed throughout the different editions of the *DSM*, the main areas of impairment (i.e., symptom domains) have remained largely

consistent. For example, deficits in interpersonal relationships, impairment in communication, and bizarre responses to the environment were the three main symptom domains in the *DSM-III*. Currently, the three main symptom domains include impairment in social interaction, impairment in communication, and restricted interests and repetitive behaviors (APA 2000).

Current Knowledge

ASD is an umbrella term used to encompass five disorders: autistic disorder (AD), Asperger's disorder (AS), pervasive developmental disorder not otherwise specified (PDD-NOS), Rett's disorder, and childhood disintegrative disorder. Given the very low incidence of these latter two conditions, the focus of this overview is related to AD, AS, and PDD-NOS. A child is referred for an assessment of ASD if developmental milestones are not met or after observations of behaviors related to diagnoses on the autism spectrum. Initial observations of symptoms or concerns regarding developmental milestones are most often made by teachers, day-care providers, pediatricians, and parents. As with other psychiatric disorders, best practices in regard to the assessment of ASD is to incorporate multiple informants and multiple methods. Informants come in the form of teachers, day-care providers, parents, grandparents, guardians, and other therapists familiar with the child (e.g., physical therapist, speech therapist). The assessment for a diagnosis of ASD should include an interview, an observation, and the administration of at least one assessment measure that has been psychometrically investigated to screen/diagnose ASD. It is also common practice to utilize measures of cognitive functioning and adaptive function to assess for a comorbid diagnosis of intellectual disability. During the entirety of the assessment sessions, clinicians assess for the triad of impairments indicative of an ASD diagnosis: deficits in communication, impairments in socialization, and the presence of repetitive motor movements (e.g., hand flapping) or intense and restricted interests (e.g., will only play with cars). Clinicians should also be mindful

of the high rates of comorbid psychopathology and challenging behaviors, and should use ASD measures that also address these issues.

More recently, there has been a move to diagnose ASD at very young ages. Fortunately, assessments designed to screen for symptoms of ASD in young populations have been developed. The measures with the best research to support them for this purpose are the *Modified Checklist for Autism in Toddlers (M-CHAT*; Robins et al. 2001) and the *Baby and Infant Screen for Children with aUtistic Traits-Part1 (BISCUIT-Part1*; Matson et al. 2007). Both measures are rating scales that can be administered in 30 min or less, have determined cutoff scores, and present with sound psychometric properties. Given the push to identify symptomatology indicative of ASD at younger ages, researchers have explored the diagnostic stability of symptoms using samples of toddlers. Outcomes of such investigations have provided support for the diagnostic stability for ASD for children under age three (Worley et al. 2011). If diagnostic status changes, it is often from one ASD to another (e.g., PDD-NOS to AD; Cox et al. 1999; Eaves and Ho 2004; Kleinman et al. 2008). Thus, at this time, research supports the need and the ability to reliably diagnose ASD during the toddler years. Diagnosing ASD at very young ages is important, as early intervention is key for long-term success.

Another factor to consider when choosing an assessment tool is the ability of the measure to differentiate between the various ASDs, given the blurred boundaries of the various disorders comprising the spectrum. The reader will note that with the appearance of the *DSM-V*, all ASDs will be collapsed together into one diagnostic category. However, for the purpose of service planning, evaluating the severity and symptom profiles will remain very important.

Although ASD can be reliably differentiated from other developmental disorders, differential diagnosis between AD, AS, and PDD-NOS remains difficult. This phenomenon is largely due to the overlapping diagnostic criteria used to define these disorders in the diagnostic nomenclature. More specifically, the diagnostic criteria for PDD-NOS are ill defined with no specific number

of criteria established to obtain this diagnosis. In addition, the diagnostic symptoms for AD and AS overlap exactly in the area of socialization and repetitive behavior and restricted interests. As a result, many researchers have examined differences between disorders comprising the spectrum. However, findings are largely inconsistent. Nonetheless, it is still important to assess for the different ASDs as a means of conforming with the current diagnostic classification system. Two measures that assist in the differential diagnosis between the various ASDs are *Autism Spectrum Disorders Diagnostic for Child (ASD-DC;* Matson and González 2007) and the *Pervasive Developmental Disorders Behavior Inventory (PDDBI;* Cohen and Sudhalter 1999). Both tests are rating scales that can be completed in 20 min or less.

In addition to the need to differentially diagnose between different psychiatric disorders, medical conditions also need to be ruled out as symptoms of certain medical conditions may simulate symptoms of certain psychiatric disorders. As such, a medical assessment should be conducted prior to making an ASD diagnosis. The most important factors to assess during the medical evaluation would be the child's hearing, vision, and oral functioning. Ruling out any problems with the aforementioned is vital to ensure that symptoms of ASD are not better accounted for by medical conditions. For example, individuals with ASD present with delays in communication and socialization. If a child is having trouble hearing or having oral motor problems, these challenges would affect their ability to speak and, subsequently, their ability to socialize with others. In addition, visual impairments could account for other symptoms such as failure to initiate and sustain eye contact and joint attention.

Lastly, intellectual disability (ID) is a highly comorbid condition with ASD. As such, the assessment process should incorporate evaluations of both adaptive skills and intellectual functioning to assess for deficits specific to these areas. Deficits in cognition and adaptive behavior are required to meet criteria for a diagnosis of ID. The assessment of intellectual functioning also assists with the differential diagnosis of

ASDs, specifically between AS and AD. For instance, individuals diagnosed with AS typically fall within the average range of cognitive functioning whereas those diagnosed with AD often have a comorbid diagnosis of ID. However, these boundaries become blurred when examining those with AS and "high-functioning autism" (HFA), most of whom have intelligence quotients (IQ) in the average range. Conversely, individuals diagnosed with AS tend to have higher verbal than performance IQs, and those diagnosed with HFA tend to have higher performance than verbal IQs.

In sum, the assessment process is conducted to arrive at a diagnosis of either AD, AS, or PDD-NOS or to rule out these diagnoses. First, AD is characterized by impairments in all three core domain areas. Children with AD are often referred for an assessment at very young ages since parents' first concerns typically arise during the first year of life. In contrast, individuals meeting diagnostic criteria for AS are often not identified until later in childhood. Likely, this is due to deficits in socialization which are the most impairing symptom associated with a diagnosis of AS. As social demands increase with age, these deficits become more pronounced and more obvious. Thus, deficits in this area become more apparent to the outside observer as the child develops and has more social interactions with others. In addition, unlike children diagnosed with AD, language development is not delayed for children meeting diagnostic criteria for AS. Instead, individuals diagnosed with AS tend to have exceptional vocabularies. Therefore, as toddlers, there is no obvious cause for concern for children eventually meeting criteria for an AS diagnosis. Lastly, a diagnosis of PDD-NOS is given when symptoms of ASD are present, but the individual does not meet the criteria for another disorder on the spectrum. Therefore, the diagnostic category of PDD-NOS is a subthreshold category. Children comprising this diagnostic category have less severe deficits in socialization and may have minimal deficits in communication or less presentation of restricted interests or repetitive behaviors when compared to a child meeting criteria for AD. In addition, it may be that these children present with the same symptoms of a child

meeting criteria for AD, but the age of onset occurs after 36 months of age.

Future Directions

The current classification system for ASD is categorical. However, this approach is problematic due to the poorly defined boundaries of the disorders comprising the autism spectrum. Due to these poorly defined boundaries, there has been a failure to find consistent differences between AD, AS, and PDD-NOS in regard to diagnostic criteria. As such, a dimensional approach to diagnosing has been proposed. This approach to diagnosing ASD is supported in the literature by researchers who have examined the underlying latent structure of symptoms of ASDs utilizing cluster analytic techniques or taxometric analyses. Although results often contradict each other, it has been suggested that the underlying taxon of ASD is dimensional (Boisjoli 2010; Verté et al. 2006).

As a result of the overlap in the behavioral phenotype of ASDs, the APA (2010) has proposed revisions for ASD to be included in the DSM-V, set to be published in 2013. The revisions include utilizing a dimensional approach to diagnosing ASD. As such, there will be no subcategories of ASD, but instead one diagnostic entity referred to as autism spectrum disorder. In regard to diagnostic criteria, impairment related to socialization and communication would be amalgamated into one domain. The second domain refers to symptoms of restricted interests and repetitive behaviors. The third domain would indicate that symptoms need to be present in early childhood; however, early childhood is not further defined. Lastly, the symptoms must cause impairment in everyday functioning (APA 2010).

These changes will bring about further modifications to the diagnostic process. For instance, parceling out differences between the various ASDs would no longer be necessary, since PDD-NOS, AS, and AD would no longer represent discrete diagnostic entities. However, given what will be even greater heterogeneity within the ASD diagnostic category, being able to identify symptom severity will still be critical. Even more

important, existing measures that assess for symptoms of ASD would need to be renormed to follow the new diagnostic criteria and continuing emerging research.

Diagnostic Substitution

Paul Shattuck

George Warren Brown School of Social Work,
Washington University, St. Louis, MO, USA

Definition

Diagnostic substitution has been hypothesized as one possible explanation for why growing numbers of children have been classified with a label of autism in publicly funded service systems such as special education and state systems of care for people with developmental disabilities. The term has been used in two related ways. One refers to a historical shift in the probability of being labeled with autism, whereby some proportion of children labeled with autism in recent years would have been classified with a different label had they been served by the same organization at a previous point in time. The other refers to individual children initially being labeled with one diagnosis and then being reclassified with autism at a later age. In each case, the hypothesis predicts that as enrollment tallies in the autism category increased, there would be some corresponding decrease in the number of children being enrolled and labeled in other administrative categories (e.g., ► [Intellectual Disability](#)).

Evidence testing the diagnostic substitution hypothesis has been mixed. One study of data from California's service system for people with developmental disabilities from 1987 to 1994 found little change in the administrative

prevalence of intellectual disability, whereas autism rates increased nearly fivefold (Croen et al. 2002; Croen and Grether 2003). Another study examined special education enrollment data from Minnesota for the years 1991–2001 and found no substantial decrease in administrative prevalence for other disabilities while autism enrollment counts were increasing (Gurney et al. 2003).

A study using state-level special education data for the whole United States found that the growing administrative prevalence of autism from 1994 to 2003 was strongly associated with decreasing prevalence in other disability categories, though not in every state (Shattuck 2006). A study of special education enrollment in British Columbia from 1996 to 2004 found that nearly one third of growing autism prevalence was explained by children who had initially been classified with some other type of disability being relabeled with autism (Coo et al. 2008).

Diastat

► [Diazepam](#)

Diazepam

Rizwan Parvez
Yale Child Study Center, New Haven, CT, USA

Synonyms

[Diastat](#); [Valium](#)

Definition

A long-acting anxiolytic medication in the benzodiazepine class. Diazepam is commonly used in the treatment of anxiety disorders, agitation, and spasticity. Diazepam and other medicines of this class bind to benzodiazepine receptors, enhancing the inhibitory effects of γ -aminobutyric acid (GABA). Side effects of benzodiazepines can include sedation, dizziness, fatigue, and confusion. Additionally, prolonged use of diazepam or other benzodiazepines may lead to tolerance and physical dependence.

DiBAS-R Validation

Tanja Sappok
Berlin Center for Mental Health in Intellectual Developmental Disabilities, Ev. Krankenhaus Königin Elisabeth Herzberge (KEH), Berlin, Germany

Synonyms

[Autism spectrum disorder \(ASD\)](#); [Diagnostic Behavioral Assessment for Autism Spectrum disorders-Revised \(DiBAS-R\)](#); [Intellectual disability \(ID\)](#); [Social communication and interaction \(SCI\)](#); [Stereotyped and restrictive behaviors and sensory interests \(SRS\)](#)

Description

The Diagnostic Behavioral Assessment for Autism Spectrum disorders-Revised (DiBAS-R) is a quick screening scale for adults with intellectual disability (ID) who are suspected of having autism spectrum disorder (ASD). It is based on the DSM-IV/5 and ICD-10 (APA 2013; Dilling 2014) criteria for ASD and consists of 19 items that are rated on a 4-point scale from “certainly true” to “never true.” It is completed by close caregivers and focuses on current behaviors within the past 3 months. Each question is worded in plain language (e.g., “Can you tell how he/she feels by his/her facial expression?” or “Does he/she show challenging behavior when unpredictable changes occur?”) to allow the administration by individuals without any specific knowledge of ASD. The scale is self-explanatory and thus does not require any preparatory training. Completion and scoring takes about 5 min.

Factor analysis indicated two subscales, namely, the *Social Communication and Interaction* (SCI) and the *Stereotypy, Rigidity, and Sensory Abnormalities* (SRS) subscale. The result of the DiBAS-R is indicative of ASD if an individual shows increased scores on the overall score (>29) and on both subscales (> 21 on the

SCI subscale and > 5 on the SRS subscale). A linear regression model revealed a significant association between the level of ID and the DiBAS-R scores, indicating an association between higher levels of ID and an increased ASD-specific symptom load. Therefore, the DiBAS-R is especially useful in individuals with mild to moderate ID. The questionnaire exists in German and English.

Historical Background

Due to the lack of appropriate screening instruments for adults with ID, a population at risk for comorbid ASD, a 20-item questionnaire, the Diagnostic Behavioral Assessment for ASD (DiBAS), was developed (Sappok et al. 2014b). It is derived from the ICD-10 and DSM-5 criteria for ASD. Information from a review of the literature focusing on symptoms that differentiate between persons with ID with and without additional ASD, an analysis of the *Autism Diagnostic Observation Schedule* (ADOS; Lord et al. 1989) items and the *Autism-Checklist* (ACL; Sappok et al. 2014c) items, and experiences from clinical experts in the field of ID and ASD endorsed the item formulation process. The items score on a 4-point ordinal Likert scale with 3 points for “certainly true,” 2 points for “often true,” 1 point for “sometimes true,” and 0 points for “never true.” The final scores range from 0 to 60 with higher scores indicating a higher ASD symptom load. These items were evaluated in terms of diagnostic validity using the final diagnostic classification of the multidisciplinary case conference as an external criterion. In a pilot study, the DiBAS was applied to 91 patients with ID and suspected ASD (Sappok et al. 2014b). The DiBAS revealed an AUC of 0.81, a sensitivity of 83%, a specificity of 64%, and a kappa of 0.47 (Sappok et al. 2014b). As 8 of the original 20 items did not differentiate sufficiently between ASD and non-ASD, in a next step, these items were replaced by another eight ICD-10/DSM-5-based questions to replenish the DiBAS-Revised (DiBAS-R).

Psychometric Data

A first study assessed the DiBAS-R in a sample that consisted of 219 adults with ID and who were suspected of having ASD who were admitted to a department of psychiatry in Berlin, Germany, from January 2012 to July 2013 (Sappok et al. 2014a). The mean age was 35 years, 57% were males, and 35% of participants were diagnosed with additional ASD. Factor analysis yielded 2 consistent dimensions with 12 items in the *Social Communication and Interaction* subscale (SCI) and 7 items in the *Stereotypy, Rigidity, and Sensory Abnormalities* subscale (SRS). The internal consistencies were *Cronbach's alpha* = 0.91 for the SCI subscale, 0.84 for the SRS subscale, and 0.91 for the overall scale. The DiBAS-R revealed sensitivity and specificity values of 81% each (Sappok et al. 2014b). The reliability was excellent: inter-rater reliability ICC = 0.88 and test-re-test reliability $r = 0.93$. The DiBAS-R scores were highly correlated with other ASD-specific measures (*Social Communication Questionnaire* (SCQ) $r = 0.52$ Berument et al. 1999; Rutter et al. 2003; *Scale of Pervasive Developmental Disorder in Mentally Retarded Persons* (PDD-MRS) $r = 0.5$ Kraijer and de Bildt 2005; *Autism-Checklist* (ACL) $r = 0.59$ Sappok et al. 2014c). The low correlation with the *Modified Overt Aggression Scale* supported the divergent validity of the instrument.

In a second study, an independent sample of 381 adults with ID and who were suspected of having ASD was recruited from August 2013 to December 2016 (Heinrich et al. 2018). The mean age was 40.5 years, 58% were males, and 24% were finally diagnosed with ASD. The diagnostic validity of the DiBAS-R including its given cutoff points was showing an overall agreement with the reference diagnoses of 70% (sensitivity, 82%; specificity, 67%). Sensitivity (79%) and specificity (84%) were more balanced in individuals with mild to moderate ID (sensitivity, 79%; specificity, 84%). Specificity decreased to 34% in persons with severe to profound ID, while the sensitivity was still good (83%). The level of ID as well as its interaction with ASD explained a significant proportion of

the variance in the DiBAS-R scores. Thus, decreasing levels of functioning may result in an increasing overlap in ASD-like symptomatology in individuals with and without ASD, which in turn may lead to a decrease in the diagnostic utility of the DiBAS-R scores.

In a third study, the combination of the DiBAS-R and the ACL were evaluated in 148 persons with ID who were suspected of having ASD (Mutsaerts et al. 2016). The specificity values increased from 75% for each instrument used alone to 88% when two positive screening results were used in combination. The sensitivity values increased from 75% for the DiBAS-R and 91% for the ACL to 95% when at least one positive screening result was used. Different combinations of the ASD screening instruments DiBAS-R and ACL lead to improvements in sensitivity and specificity. The instruments can therefore be used in a complementary way to further improve the overall accuracy of each scale.

Clinical Uses

The DiBAS-R can be used as a quick screening instrument for ASD in adults with ID. It is easy to administer and can be applied in various settings, e.g., hospitals or outpatient clinics or in population-based studies. No special knowledge of the diagnostic criteria of ASD is needed to complete the questionnaire, and no training is necessary to compute the final scoring. Thus, the scale can be used by general practitioners, psychiatrists, or psychologists to screen for ASD in research and clinical practice. The administration of the scale requires about 5 min for scoring and computing and is independent of the collaboration of the examined individual. The validity and reliability results suggest that this scale represents an efficient approach to initial ASD screening of adults with ID. However, it cannot replace a comprehensive assessment for ASD such as interview-based procedures like the Autism Diagnostic Interview-Revised (ADI-R; Lord et al. 1994) or direct behavioral observations in a standardized setting like the Autism Diagnostic Observation Schedule (ADOS; Lord et al.

1989). Its psychometric properties particularly support its use in persons with mild to moderate ID. The DiBAS-R can be applied for clinical and research purposes.

Dichotic Listening

Jennifer McCullagh

Department of Communication Disorders,
Southern Connecticut State University, New
Haven, CT, USA

Description

Dichotic listening is the auditory process that involves listening with both ears. Dichotic listening can be broken into two different processes: binaural integration and binaural separation. Binaural integration is the ability to perceive different acoustic messages presented to the left and right ears at the same time. Binaural separation is the ability to perceive an acoustic message in one ear while ignoring a different acoustic message in the other ear. In order to perceive the acoustic messages in both ears, the outer, middle, and inner ears must be working properly, but more importantly, the auditory brainstem nuclei, auditory cortical neurons, as well as neurons in the corpus

callosum must be functioning properly. Individuals with dichotic listening deficits often have difficulty hearing in the presence of background noise.

Historical Background

Dichotic speech testing was first introduced by Broadbent in 1954. It requires the simultaneous presentation of different speech stimuli to each of the ears; the listener must repeat back everything that is heard (binaural integration) or what is heard in one ear only (binaural separation). In 1961, Kimura first used these tests to demonstrate hemispheric asymmetry and cortical dysfunction. She demonstrated contralateral auditory deficits following temporal lobe lesions. These findings indicate that if a lesion is located in the left temporal lobe, the auditory signal presented to the right ear will not be perceived. In typical individuals (those with normal hearing and no known lesions in the central auditory nervous system), a right ear advantage has consistently been reported (Berlin et al. 1973; Dirks 1964; Kimura 1961a, b). Right ear advantage refers to the ability to better perceive the auditory signal presented to the right ear than the speech signal in the left ear. The right ear advantage exists because the hemisphere in the brain responsible for processing the speech signal is in the left hemisphere. Since the contralateral pathways are stronger, the speech signal presented to the right ear travels directly to the left hemisphere for processing; however, the speech signal presented to the left ear must travel to the right hemisphere and across the corpus callosum to the left hemisphere to be processed (creating a slight time delay).

Currently, a variety of dichotic listening tests are available for clinical use. Common dichotic speech tests, specifically binaural integration tests, are the Dichotic Digits Test (Musiek 1983; Musiek and Wilson 1979; Musiek et al. 1979); the Staggered Spondaic Word Test (SSW; Katz 1962), and Dichotic Consonant-Vowels (Dichotic CVs; Berlin et al. 1973). Some common

binaural separation tests are Competing Sentences (Willeford 1977) and the Synthetic Sentence Identification with Contralateral Competing Message (SSI-CCM; Jerger 1970).

Psychometric Data

Dichotic listening tests, such as the Dichotic Digits, Dichotic CVs, SSW, Competing Sentences, and SSI-CCM, have been shown to be sensitive and specific to central auditory nervous system lesions, including interhemispheric lesions (for review, see Musiek and Pinheiro 1985). Peripheral hearing sensitivity should be symmetrical and normal when using dichotic listening tests since any hearing differences between ears can influence test results.

Clinical Uses

Dichotic listening tests are used in clinical audiology to evaluate the central auditory processes of binaural integration and separation. These tests may be used in the assessment of children or adults with possible central auditory nervous system dysfunction. Since dichotic listening tests (tests of binaural integration and separation) evaluate two critical auditory processes, it is important for these tests to be included in a central auditory processing test battery. Clinically, the person administering dichotic listening tests should take into consideration the cognitive, hearing, speech, and language abilities of the individual being tested as these factors may affect performance. Thus, dichotic listening tests are not typically administered to children with autism, and performance on these tests should be interpreted with caution in this population.

Didactic Approaches

Sarita Austin

Unlocking Language, London, UK

Synonyms

[ABA](#); [Adult-/clinician-/teacher-directed approaches](#); [Behavioral approaches](#); [Direct instruction](#)

Definition

A *didactic approach* to teaching refers to a manner of instruction in which information is presented directly from the teacher to the pupil, in which the teacher selects the topic of instruction, controls instructional stimuli, obligates a response from the child, evaluates child responses, and provides reinforcement for correct responses and feedback for incorrect ones. Intervention methods for early communication in children with autism spectrum disorder (ASD) are often divided into three categories: didactic, naturalistic, and pragmatic or developmental.

Didactic approaches utilize a variety of concepts from behavioral theory, including massed trials, operant conditioning, shaping, prompting, chaining, and reinforcement. Difficulty with the generalization and maintenance of behaviors learned through this method along with the passive communication acquired by many children (i.e., waiting on adults' lead during interactions) are some of the drawbacks associated with this approach. Still, the effectiveness of this approach in initiating and expanding expressive language and developing attention to language and comprehension in preverbal children with ASD is supported by research from numerous case studies and several group studies.

As this approach requires a notable amount of adult direction, a passive role as responder by the child, repetitive drills and

practice, and specific events that should occur before and after a child's response, this method is ideally effective if the instructor consistently monitors the student's interest level, readiness for the information being conveyed, and the motivational value of reinforcers. The passivity and prompt dependence that can result from these methods led to the development of more naturalistic instructional techniques (e.g., contemporary applied behaviors analysis).

Differential Ability Scales

- [Differential Ability Scales \(DAS and DAS-II\)](#)

Differential Ability Scales (DAS and DAS-II)

Celine A. Saulnier

Department of Pediatrics, Emory University
School of Medicine, Atlanta, GA, USA

Synonyms

Cognitive measures; DAS; DAS-II; Differential ability scales

Description

The Differential Ability Scales, Second Edition (DAS-II; Elliott 2007) is an individually administered test designed to measure distinct cognitive abilities for children and adolescents ages 2 years, 6 months to 17 years, 11 months. The DAS-II is comprised of individual subtests that evaluate strengths and weaknesses of a broad range of learning processes. A General Conceptual Ability (GCA) composite score is generated that reflects conceptual and reasoning abilities. Three cluster scores of the DAS-II measure more specific learning processes: verbal, nonverbal reasoning, and spatial abilities. There is also a Special Nonverbal Composite that can be derived for an individual of any age where the verbal demands are too taxing to obtain standardized results. The core subtests of the DAS-II tap into specific cognitive processes that are used to estimate the cluster and GCA scores, and the abilities they assess are directly related to educational needs at each age range. There are also Diagnostic subtests that measure memory, processing speed, and early school learning abilities. These scores do not contribute to the overall cluster or GCA scores; however, they are still important foundational skills that address a child's profile of cognitive strengths and weaknesses, as well as educational needs.

Core Batteries of the DAS-II

There are two batteries of the DAS-II: Early Years and School Age. Within Early Years, there are two

levels. The first level is for children ages 2 years, 6 months through 3 years, 5 months. This lower level consists of 4 core subtests (*Verbal Comprehension* [VCom], *Naming Vocabulary* [NVoc], *Picture Similarities* [PSim], and *Pattern Construction* [PCon]) and yields a Verbal Ability (VCom + NVoc) and Nonverbal Ability (PSim + PCon) cluster score, as well as the GCA. The upper level is for children ages 3 years, 6 months to 6 years, 11 months and has 6 core subtests (VCom, NVoc, PSim, *Matrices* [Mat], PCon, and *Copying* [Copy]) that yield three cluster scores: Verbal Ability (VCom + NVoc), Nonverbal Ability (PSim + Mat), and Spatial Ability (PCon + Copy), as well as the GCA.

The School-Age battery of the DAS-II can be administered on children ages 7 years, 0 months to 17 years, 11 months, and it is comprised of six core subtests (*Word Definitions* [WDef], *Verbal Similarities* [VSim], Mat, *Sequential and Quantitative Reasoning* [SQR], *Recall of Designs* [RDes], and PCon) that yield three cluster scores: Verbal Ability, Nonverbal Reasoning Ability, and Spatial Ability, as well as the GCA.

Both the Early Years and School-Age batteries of the DAS-II are normed on children between the ages of 5 years, 0 months and 8 years, 11 months. This allows the School-Age subtests to be administered for brighter young children and, in contrast, the Early Years subtests to be administered for older, less cognitively able children.

Diagnostic Subtests of the DAS-II

The Early Years battery of the DAS-II consists of the following ten Diagnostic subtests: *Early Number Concepts* [ENS], *Matching Letter-like Forms* [MLLF], *Phonological Processing* [PhP], *Recall of Sequential Order* [SeqO], *Recall of Digits Forward* [DigF], *Recall of Digits, Backward* [DigB], *Speed of Information Processing* [SIP], *Rapid Naming* [RNa], *Recall of Objects – Immediate and Delayed* [ROBI, ROBD], and *Recognition of Pictures* [RPic]. Seven of these subtests contribute to three cluster scores: School Readiness (ENC + MLLF + PhP), Working Memory (SeqO + DigB), and Processing Speed (SIP + RNa).

The School-Age battery of the DAS-II only consists of seven Diagnostic subtests that yield

two cluster scores: Working Memory (SeqO + DigB) and Processing Speed (SIP + RNam). The School Readiness subtests from the Early Years battery are not included in the School-Age norms, with the exception of PhP, which has norms up to age 12 years, 11 months.

Historical Background

The original Differential Ability Scales (DAS; Elliott 1990) was modeled after the British Ability Scales (BAS; Elliott et al. 1979). Both instruments were unique in the field of intelligence tests in that their focus was on distinct subtest scores that could be used to flush out cognitive profiles of strengths and weaknesses rather than on an overall intelligence quotient or estimation of IQ. This conceptualization of cognitive assessment sets the DAS and subsequent second edition (DAS-II; Elliott 2007) aside from other commonly used measures, such as the Wechsler Intelligence Scale for Children, Fourth Edition (WISC-IV; Wechsler 2003) or Stanford-Binet Intelligence Scales, Fifth Edition (SB5; Roid 2003), where the theoretical models tend to focus more on generalized intelligence than on distinct cognitive abilities. Nevertheless, the DAS and DAS-II have an overall composite score that reflects general cognitive functioning (i.e., General Conceptual Ability score) and that is derived from those subtests which load highest on the factor of general intelligence, or *g*. This results in the GCA being a more refined score than other measures of global intelligence that are derived from a broader collection of subtests. However, examiners are cautioned against interpreting the GCA as a global measure of functioning, as many children have a variable cognitive profile that one general score cannot appropriately encapsulate. This is particularly the case for children with autism spectrum disorders (ASD), where scatter within a cognitive profile is the norm rather than the exception (e.g., Klin et al. 2005).

Although the theoretical development of the BAS, DAS, BAS-II (Elliott 1996), and DAS-II

predated theoretical work on the Cattell-Horn-Carroll theory of intelligence (CHC; McGrew 2005), the structure of the DAS-II fits well into the seven-factor CHC model. For instance, the DAS-II Verbal Ability cluster measures crystallized intelligence (*Gc*), the Nonverbal Reasoning cluster measures fluid intelligence (*Gf*), the Spatial Ability cluster measures visual-spatial processing (*Gv*), the Working Memory diagnostic cluster measures short-term memory (*Gsm*), the Recall of Objects subtest measures long-term storage and retrieval (*Glr*), the Processing Speed cluster measures cognitive processing speed (*Gs*), and the Phonological Processing subtest measures auditory processing (*Ga*).

Psychometric Data

The DAS-II has been standardized on a normative sample of 3480 children ages 2 years, 6 months to 17 years, 11 months that is representative of the general population. Data are also available for a range of clinical samples, including developmental risk, learning disabilities, attention deficit/hyperactivity disorder, mild to moderate intellectual disability, and the gifted and talented.

On the DAS and DAS-II, Verbal, Nonverbal, Spatial, and Special Nonverbal cluster scores, as well as the GCA score, are reported in standard scores that have a mean of 100 and standard deviation of 15 and that range from 30 to 170. Individual subtest scores are reported as T scores that have a mean of 50 and a standard deviation of 10 and that range from 10 to 90. T scores are derived from ability scores, which are based on the number of correct responses (i.e., the raw scores) and on the difficulty of administered items, following the Rasch Model of item response theory. The administration and scoring system of the DAS and DAS-II is also different from other common measures in that raw scores are computed based on the number of items administered within a response set, rather than calculating this number in addition to items

below the basal. In this way, children are administered only those set of items that are appropriate in difficulty to their ability level. Subtest scores can be presented as age equivalents that represent the median ability score for each child's performance, and descriptive categories are provided for standard scores that range from "Very High" (70 and above) to "Very Low" (69 and below).

The DAS-II has strong internal reliability, with average reliability coefficients for the Early Years subtests ranging from .79 to .94 and for the School-Age subtests ranging from .74 to .96. The average reliability for the DAS-II GCA is .95 for Early Years and .96 for School Age. Confirmatory factor analyses were conducted to assess the internal validity of the DAS-II, and general results confirmed the existing clusters; for instance, the structure of cognitive abilities varies with age, with fewer models emerging for the youngest children (e.g., Verbal and Nonverbal clusters) and additional models emerging with age (e.g., Spatial, Short-term Memory, and Cognitive Speed clusters).

Correlations between the DAS and DAS-II are strong, with .88 for the GCA and .85 for the SNC. The correlation between the DAS-II GCA and the Wechsler Preschool and Primary Scale of Intelligence, Third Edition (WPPSI-III; Wechsler 2002) Full Scale IQ is .87; however, WPPSI-III Index and FSIQ scores range from 1.7 to 5.1 points higher than DAS-II cluster scores. WISC-IV Index and FSIQ scores also range from 1.2 to 6.6 points higher than DAS-II cluster scores, with a correlation coefficient of .84 between the two measures.

In nonclinical samples, the correlation between the DAS-II GCA and measures of academic achievement is as follows: .82 with the total score of the Wechsler Individual Achievement Test, Second Edition (WIAT-II; Harcourt Assessment 2005); .81 with the Comprehensive Achievement Composite of the Kaufman Test of Educational Achievement, Second Edition (KTEA-II; Kaufman and Kaufman 2004); and .80 with the Total Achievement score of the

Woodcock-Johnson III Tests of Cognitive Abilities (WJ-III; Woodcock et al. 2001).

Clinical Uses

There are several clinical benefits to using the DAS-II when assessing individuals with autism spectrum disorders (ASD; Klin et al. 2005; Saulnier et al. 2011). These advantages include the following:

1. The teaching items that are provided within each DAS-II domain are extraordinarily useful when complex instructions impede a child's ability to comprehend a given verbal request. When the examiner is allowed to model or demonstrate the correct response, the child is better able to comprehend the nature of the task and successfully complete a subtest on which they otherwise might have failed to obtain a basal level of performance.
2. The extended norms on the DAS-II Early Years battery allow for obtaining standard scores for older, more impaired individuals through age 8 years, 11 months – an option not available in other measures (Elliott 2007).
3. The extended norms of the School-Age battery down to age 5 allow for adequately testing younger children with ASD with more advanced cognitive skills.
4. The Special Nonverbal Composite makes it particularly appealing for individuals on the autism spectrum with significant language vulnerabilities for whom the language demands on the verbal tasks are too taxing. The SNC is also useful for other unique samples, such as children with speech, language, and/or hearing impairments or children who are not fluent in English.
5. The results can generate recommendations for educational and treatment programming that are clinically relevant to each child.

The DAS-II is also extremely useful for clinical research in ASD. First, the extensive age range

makes it possible to conduct scientific studies on both cohort and longitudinal studies of children between the ages of 2 and 17. Second, the extended norms allow for utilizing the same battery for varying levels of functioning. Finally, the core subtests can be administered quickly while generating a more comprehensive measure of cognitive functioning than an abbreviated measure of intelligence.

There have been several studies using the DAS that highlight its utility in detecting learning disabilities and cognitive delays. For instance, in one study comparing composite scores between the DAS and WISC-III, children with learning disabilities evidenced a specific weakness in the Nonverbal Reasoning cluster of the DAS that was not demonstrated on the Perceptual Reasoning Index of the WISC-III (Dumont et al. 1996). The majority of research on cognitive profiles in autism spectrum disorders (ASD) has been conducted using the Wechsler Scales. Less research has investigated DAS and DAS-II profiles in ASD, despite the fact that many researchers have used both measures as part of the characterization process for research paradigms. A study conducted by Joseph, Tager-Flusberg, and Lord (2002) used the DAS on a longitudinal sample of children with and without ASD. They found that the majority of preschool-aged children exhibited lower verbal than nonverbal cluster scores and that greater discrepancies between verbal and nonverbal abilities were detected in ASD vs. the normative sample, with this gap widening with age. Furthermore, children with larger gaps between their verbal and nonverbal skills had greater social impairments, and impaired social functioning was independent of their verbal skills.

Differential Reinforcement

Thomas Zane

Van Loan School of Graduate and Professional Studies, Endicott College, The Institute for Behavioral Studies, Beverly, MA, USA
Department of Applied Behavior Science, University of Kansas, Lawrence, KS, USA

Definition

Differential reinforcement is the process of reinforcing a specific response in a particular context and not reinforcing (i.e., extinguishing) other responses. More specifically, differential reinforcement involves providing either positive or negative reinforcement for a targeted response (or targeted member of a response class) and withholding reinforcement from all other responses (or members of a response class). The withholding of reinforcement is defined as “extinction.” Thus, differential reinforcement is a two-part process – reinforcing the desired response(s) and extinguishing all other responses. For example, a parent might reinforce with praise a young child calling out the mother’s name and ignoring (and thus not reinforcing) the child’s behavior of hitting the parent. Another example would be a teacher reinforcing (with praise and attention) a child raising her hand before being called upon to answer a question and ignoring that child if she were to shout out the answer without raising her hand. The goal of differential reinforcement is to increase the strength of the response being reinforced, while weakening the strength of the other responses not being reinforced.

Current Knowledge

A basic principle in understanding differential reinforcement and how people learn in most situations is the concept of discrimination. Basically, discrimination is a process for behaving one way in one situation or context, and behaving in a

completely different way in a different situation or context. Thus, discrimination is the ability to tell the difference between environmental events (or contexts or cues) and behaving accordingly. Discrimination typically develops as a result of differential reinforcement.

Almost all learning occurs due to the concept of discrimination and differential reinforcement. For example, consider learning the letters of the alphabet. When the letter “B” is shown and the learner asked to identify the letter, indicating “B” will be reinforced and naming any other letter will not be. This process of differentially reinforcing the learner’s responses (as correct and incorrect) results in learning of the alphabet. Consider learning to speak. When an infant says “mama” in the presence of the mother, that response will be reinforced with smiles, hugs, and positive attention. If the infant says “mama” in the presence of the father, there will be no reinforcement. Differentially reinforcing a response in one context (i.e., in presence of the mother) and not in another (i.e., in the presence of the father) results in the baby learning what to say in the presence of each parent. Consider the acquisition of social behaviors. Some young children refuse to share their toys. When this occurs, the adult rarely reinforces such selfishness. However, when a child does in fact share her toys, adults provide positive attention and reinforcement. In this case, the adult responds differently to two different behaviors – sharing and not sharing. Through this process, the child learns that sharing is preferred and hoarding toys is not. Thus, virtually all learning is accomplished through the process of learning discriminations via differential reinforcement.

The procedure of differential reinforcement has been used to both increase and decrease the strength (future rate) of specific behaviors. However, even though the goals are different (when considering increasing or decreasing future rates of behaviors), the procedure of differential reinforcement is the same. The basic procedural components of all differential reinforcement programs are these. First, the interventionist must operationally define the target behavior to be changed. That could be an appropriate behavior that must be increased in rate, a behavior deemed inappropriate

that must be decreased in rate, or both. The behavior must be operationally defined to allow for both correct recording of its occurrence (so the interventionist can objectively determine if the differential reinforcement procedure is having the desired effect) as well as for accurate implementation of the procedure (i.e., so that the interventionist(s) reinforce (or not reinforce) the correct response).

The second step in using differential reinforcement is to determine the actual reinforcement that will be made contingent upon the required response. This, by necessity, will vary across the individual due to the fact that what constitutes a motivating reinforcer is so personalized across individuals. However, most of the time, the interventionist will use some form of positive reinforcement, such as praise, smiles, good grades, tokens, or other forms of tangible reinforcement found desirable by the individual. On occasion, the interventionist might use a form of negative reinforcement, such as allowing the individual to escape a work demand contingent upon displaying the targeted response. For example, in the case where an individual tantrums in order to escape or avoid work, the caregiver might allow that person to take a break from work if the individual asks for a break instead of tantruming. Allowing the individual to briefly escape an unpleasant work demand negatively reinforces asking for a break. However, if the individual continues to tantrum and does not ask appropriately for a break, the caregiver would continue to keep the person in the demand situation by requiring work. The use of formal reinforcement preference assessments is considered best practice to determine the most motivating reward items available.

The last step in the procedure is to determine if and how reinforcement can be withheld from the individual when she/he displays a behavior other than the targeted one. In the case of using differential reinforcement to increase the strength of an appropriate behavior, the interventionist must only reinforce the targeted appropriate behavior. In the example of a child shouting out answers instead of raising a hand, the teacher will reinforce hand raising but will have to decide exactly how

to respond to the shouting out of answers. The interventionist will need to ensure that no positive reinforcement follows any behavior other than the targeted one. An important question is whether the inappropriate behavior can be ignored. In the case of shouting out an answer, it is probably the case that planned ignoring can be used effectively. However, in other situations, with other behaviors such as self-injury or aggression, planned ignoring may be difficult.

There are many variations of differential reinforcement procedures that have been used. The most common ones are differential reinforcement of alternative behaviors (DRA), differential reinforcement of incompatible behaviors (DRI), differential reinforcement of other behaviors (DRO), and differential reinforcement of low rate behaviors (DRL; see “See Also” section, below).

Differential reinforcement is one of the most widely used procedures to change behavior. The treatment of problem behaviors has evolved to the point that there is a common assumption that reinforcement-based procedures are considered to be best practice and the most ethical strategies to implement. The procedure is a natural one to most interventionists, in which desired behaviors are rewarded and all other behaviors not rewarded. The research has shown that differential reinforcement procedures can be very effective in changing behaviors, and – since they are based on the use of reinforcement (most of the time, positive, as opposed to negative) – many caregivers are comfortable with using such interventions. An advantage of differential reinforcement procedures is that caregivers have a systematic way to implement a technique that focuses on appropriate (positive) behaviors. Another advantage is that such procedures maintain a positive learning atmosphere and allow the instructional (or work activities) to continue in the context in which these procedures are used. A third advantage is that differential reinforcement can be effective without the addition of aversive or unpleasant procedures, such as punishment. Differential reinforcement is also a good procedure to implement when targeting problem behaviors due to the fact that this procedure can be used before and after the

administration of functional assessment strategies to determine the function of that behavior. In these cases, differential reinforcement can possibly establish appropriate replacement behaviors, by orienting staff to notice and reinforce desired behaviors. This is important because differential reinforcement procedures do not address the function of challenging behaviors. That is, these procedures are used in an attempt to “override” the reinforcing function of problem behaviors.
